Chemical Engineering

Metallurgical & Chemical Engineering

A Semi-monthly Technical Newspaper,
Being the Incorporation of
Electrochemical and Metallurgical Industry
and Iron and Steel Magazine

Volume XIV

From January 1 to June 15, 1916

436 839
3. 7. 45

NEW YORK:
McGRAW PUBLISHING COMPANY, Inc.

INDUSTRY VOLUME XIV

GENERAL ALPHABETICAL INDEX

Entries from the Synopsis of Periodical Literature are indicated by S. (Synopsis); from the Analysis of Current Electrochemical, Chemical and Metallurgical United States Patents by P. (Patents); from the Digest of Electrochemical United States Patents Prior to July, 1902, by D. (Digest).

A

Ablé, Paul O. Mixer..... 667
 Abrasives..... 46, 510
 Academic military..... 557
 Accidents at metallurgical works during 1913 and 1914..... 562
 Accidents. Two instructive accidents from chemical engineering practice. Report..... 66
 Acetic acid. By electrolysis of acetylene. Hanson and Weindel. (P.)..... 101
 Acetylene. Electrolysis of. Hanson and Weindel. (P.)..... 101
 Acheson Graphite Co..... 289
 Acids: See under Sulphuric, nitric, etc.
 Acid proof iron..... 551
 Acid tank car. Accident with. Rupert..... 66
 Aesthetics and science..... 200
 Aetna Chemical Co..... 269
 Aetna Explosives Co..... 269
 Air: Fixation of nitrogen from air. See Nitrogen Fixation
 Air. Liquid. Production of. Marchis..... 187
 Air Reduction Co..... 715
 Air separation. Wiard..... 92
 Akms classifier..... 92
 Alcohol. Extension of time for awards by Russia..... 345
 Alcohol. From waste sulphite liquor..... 669
 Alexander, D. B. W..... 170
 Alkali deposits of California and Oregon..... 359
 Alkaline storage battery. Use of cerium. Edison. (P.)..... 282
 Allantite. Radio-activity of. Pratt..... 484
 ALLOYS:
 —Aluminum-magnesium. Naylor and Hutton. (P.)..... 546
 —Copper alloy. Pease. (P.)..... 222
 —Ductile alloys of tungsten, thorium and platinum. Kaiser. (P.)..... 283
 —Electric-resistor material. Hunter. (P.)..... 222
 —Gold alloys, substitute for platinum and palladium alloys. Richter. (P.)..... 283
 —Iron and hydrogen for anodes and cathodes. Gesner. (D.)..... 232
 —Lead and alkaline earths. Fry and Temple. (P.)..... 107
 —Silver-palladium as platinum substitutes. Heyl. (P.)..... 164
 ALUMINUM:
 —Auto engine castings..... 113
 —Magnesium alloys. Naylor and Hutton. (P.)..... 546
 —Melting of. Mellen. (P.)..... 221
 —New Japanese plant..... 402
 —Nitride. Electric furnace production. Couteaux. (P.)..... 100
 —Process of producing alumina. Schwahn. (P.)..... 545
 —Production in 1915..... 96
 —Production from clay and other silicates. Mellen. (P.)..... 221
 —Proposed Norwegian plant..... 553
 —Special coating..... 459
 —Statistics..... 113, 510
 —Treating aluminium scrap. Lawrie. (P.)..... 101
 —Welding sheets in automobile work..... 548
 Aluminum company of America..... 506
 Amalgamation. Central mill of North Star Mines Co. Palmer..... 35
 —New dry amalgamator. Palmer..... 715
 American Blower Co..... 172
 American chemical industry in 1915..... 1

American Chemical Society.
 —New York Section..... 300
 —Nichols medal presentation..... 413
 —University and industry..... 413
 —Program of meeting..... 630
 —Last meeting of season 1915-1916..... 678
 —Urbana meeting and exhibition, 210, 268, 358, 411
 —Report..... 485
 American Coal Products Company..... 289
 American Coal Refining Co..... 416
 American Cyanamid Co..... 172, 418
 American Electrochemical Society:
 —New York Section..... 130, 180, 465
 —Electrochemical war supplies..... 259
 —Flotation..... 569
 —Pittsburgh Section..... 290
 —Washington general meeting, 357, 410, 473
 American Gas & Electric Co..... 110
 American Institute of Chemical Engineers:
 —Baltimore meeting..... 159
 —Announcement of Cleveland meeting..... 464
 —Program of Cleveland meeting..... 623
 American Institute of Electrical Engineers:
 —Corrosion..... 300
 —Waterpower conference..... 469
 —Installation..... 11, 130, 173, 245
 —Resolutions on Chihuahua murder..... 130
 —Arizona Section..... 331
 —Montana Section..... 290, 332
 —New York Section..... 358, 465
 —Nevada Section. Announcement of installation..... 554
 —St. Louis Section—Annual meeting..... 668
 American Iron and Steel Institute..... 465, 629
 American Metal Products Co..... 172
 American Paper and Pulp Association—Annual meeting..... 130
 American Products Co..... 356, 554
 American Smelting & Refining Co. 22, 174, 624
 —Election of directors..... 553
 American Society of Mechanical Engineers—Spring meeting at New Orleans..... 375
 American Society for Testing Materials..... 347
 American Steam Pump Co..... 233
 American Steel & Wire Co. starts by-product coke plant..... 554
 American Synthetic Dyes, Inc. Engineers..... 559
 American Zinc, Lead & Smelting Co..... 416
 AMMONIATES:
 —From coal gas. Wagner..... 495
 —From nitric acid. Landis..... 513
 —Nitric acid from, by Ostwald process. Schuphaus..... 425
 —Production from cyanamid. Landis..... 87
 —Solubility of naphthalene. Hilpert. (S.)..... 709
 —Synthetic..... 395
 —Tungsten as catalyst. Bosch. (P.)..... 712
 Ammonium sulphate manufacturer. Use of nitre cake..... 564
 Anaconda Copper Co..... 132
 —Electrolytic zinc plant..... 132
 —Flotation. Laist and Wiggins..... 329
 —Progress..... 416
 ANALYSIS:
 —Carbon dioxide. Pocker indicator..... 402
 —Chain vernier analytical balance..... 230
 —Copper in copper-manganese. Electrolytic. Koeping..... 441
 —Copper. Some sources of error in iodometric determination..... 379
 —Rubber gums. King..... 581
 —Testing volumetric apparatus..... 580
 —Zinc. Proposed quick method for re-tort residues or electric furnace slags. Johnson..... 395
 —Zinc retort-residue..... 200

Aniline Dyes: See Dyestuffs.
 Annealing of metals. Thompson..... 679
 Anthony, Richard A..... 147
 ANTIMONY:
 —Behavior of stibnite in an oxidizing roast. Hofman and Blatchford. (S.)..... 163
 —Determination in roasted stibnite. Hall and Blatchford. (S.)..... 164
 —New eastern smelting plant..... 613
 —Production in 1915..... 172
 —Production in Hunan Province, South China. Wheeler. (S.)..... 374, 538
 Antimonial gold ore treatment. (S.)..... 54
 Apollo Electric Steel Co..... 233
 Arizona copper strike ended..... 124, 177
 Arizona Copper Company. Fire loss..... 14
 Armstrong Cork & Insulation Co..... 113, 347, 551
 Arsenic. Production in 1915..... 114
 Asbestos. Use of grading..... 578
 Asbestos. Production..... 718
 Asbestos Protected Metal Co..... 403
 Asphalt and asphalt products. Pierce..... 519
 Asphalt primer..... 215
 Assaying. Distribution of silver between metallic lead and litharge-containing slags. Dudley..... 636
 —Effect of litharge. Dudley..... 695
 Assaying. Geological Survey cannot make assays..... 23
 Atwater, C. G..... 403

B

BACHARACH Industrial Instrument Co. 402
 Bacon, Raymond F..... 553
 Baekeland, L. H..... 458
 Bailey Meter Co..... 172, 456, 667
 Baker cooler..... 149
 Bakelite. Early history..... 166
 Balance..... 717
 Ball-mill. Development of..... 285
 Ball mills. Need of data..... 292
 Banker. The chemist and..... 174
 Barber Asphalt Paving Co.'s laboratory organization..... 519, 580
 Barium. Industry since the war. Toch..... 47
 Barium. Industry in United States. Toch..... 159
 Barium. Old barytes plant re-opened..... 289
 Barrett Company..... 289
 Baruch, Edgar..... 115
 Barytes. Use of grading..... 578
 Barytes. Production..... 713
 Battery. Cerium used in alkaline battery. Edison. (P.)..... 283
 Bausch & Lomb Optical Co..... 289
 Bauxite statistics..... 113
 Bavarian porcelain..... 233
 Becker chain balance..... 230
 Belgium. Chemical industries of. Hubert..... 376
 Belts. Nomographic charts for calculations. Haylett..... 8
 Benson, H. K..... 346
 BENZOL:
 —Brier Hill Steel Co..... 347
 —From coal gas..... 496
 —From petroleum. Rittman process..... 269
 —Koppers Co. erections of by-product coke ovens..... 347
 —Present rate of production..... 601
 —Production in 1915..... 162
 —Production from low-grade coal tar oils. Rittman and Egloff..... 15
 Benzol products Company..... 289
 Binnett, L. G. E..... 716

Rismuth Purification. Smith, (F.).....	222
Bljorkstekt, Wm.....	170
Blake, Lucien I.....	614
Blast furnace. See Furnace, Blast.....	
Blauvelt, Warren F.....	613
Bleaching of sulphur pulp. Plant for.....	612
Bleaching. New process. Peckham.....	160
Bleaching with liquid chlorine.....	217
Blomfield, A. L.....	403
Blower, Boston type for flotation smelter work.....	58
Boeck, P. A.....	170
Boiler meter. Combination.....	667
Bomb furnace. Electrical. Calhoun and Lavene.....	140
BOOK REVIEWS:	
—Bauer and Deiss. Sampling and Chemical Analysis of Iron and Steel Translated by Hall and Williams.....	62
—Burgess and Cravens. Applied Electrochemistry and Welding.....	460
—Cosgrove. Coal: Its Economical and Smokeless Combustion.....	614
—Edelman. Inventions and Patents.....	234
—Franklin and MacNutt. Elementary Electricity and Magnetism.....	116
—Hore. Canadian Mining Manual, 1915.....	670
—Howe. Metallurgy of Steel and Cast Iron.....	556
—Johnstone. Rare Earth Industry.....	62
—Kautny. Autogeneous Welding and Cutting. Translated from the German by the author and James F. Whitford.....	234
—Liddell. Metallurgists and Chemists Handbook.....	718
—Mechanical World. Electrical Pocket Book for 1916.....	404
—Norris. Experimental Organic Chemistry.....	116
—Osann. Lehrbuch der Eisenhüttenkunde. Vol. I. Roheisenherzeugung.....	614
—Park. Textbook of Practical Assaying.....	718
—Richards. The Flotation Process.....	670
—Sauveur. Metallurgy and Heat Treatment of Iron and Steel.....	404
—Scott. Journal of the Institute of Metals.....	350
—Skinner. Mining Manual and Mining Year Book for 1915.....	350
—Spiegel. Chemical Constitution and Physiological Action. Translated by Laedeking and Belderson.....	62
—Stansbie. Elementary Practical Metallurgy.....	718
—Stansfield. Electrothermic Smelting of Iron Ores in Sweden.....	62
—Wagner. Coal and Coke.....	460
—Woodman. Food Analysis.....	116
Borax. Use of grading.....	578
Boric. Flotation.....	327
Boron nitride. Stable product. Weintraub, (P.).....	101
Boston Hose and Rubber Co.....	60
Bostwick, F. H.....	170
Bourne, F. P.....	346
Braden Copper Co.....	344
Braden Copper Co. Metallurgical methods. Douglass and Colley, (S.).....	279
Bradley, P. K.....	115
Brake. Magnetic clutch.....	60
Brashear, John A.....	64
Brier Hill Steel Co.....	347
Brinell hardness testing machine. Scimitar.....	58
Brinell hardness tester. Improved.....	612
Briquet production in U. S.....	554
Briquetting processes. Bibb, (P.).....	102
Bristol Co.....	107
Bromine wells in operation.....	290
Bronze. Annealing zinc bronze.....	290
Brown, Alexander C.....	613
Brownell, F. H.....	290
Brownson, E. E.....	669
Brunner, Mond & Co.....	113
Buffalo Potash & Cement Corporation.....	13
Bunker Hill & Sullivan. New smelter.....	13
Bureau of Mines.....	
—Co-operation with Colorado School of Mines.....	241
—Fifth annual directors' report.....	167
—Work on chemical and metallurgical from petroleum.....	269
Burger, Clarence L.....	670
Burgess, C. F. Laboratories.....	460
Burns, W. T.....	290

C

CADMIUM. Removal from zinc ores. Rieg, (P.).....	220
Calcium carbide.....	510
Calcium carbide. New American plant in Norway.....	564
Caldwell & Son Co., H. W.....	113
California.....	
—Mineral resources.....	114
—University of. Chemical engineering course.....	613

CALIFORNIA: (Continued.)	
—University of. New building construction.....	460
Calorimeters. Standardization.....	45
Calumet & Arizona Mining Co.....	624
Camden Coke Co. Coke ovens and benzol.....	347
Camp Bird, Ltd.....	242
Canada.....	
—Clay products, cement and lime.....	347
—Department of Mines in 1914.....	348
—Mineral production in 1915.....	344
—Mines Department laboratories.....	518
—Mining Institute. Annual session.....	146
—Mining Institute. Ottawa meeting.....	323
—Niagara Falls and industrial Canada.....	351
—Research Bureau.....	669
Canning. Use of grading.....	579
Carbon articles and electrodes. Cemented. Brown, (F.).....	101
Carbon dioxide pocket indicator.....	402
Carcolite Chemical Co. to rebuild plant.....	554
Carnotite. Radio from.....	51
Carnotite ore. Separation of vanadium from crude sodium uranate.....	177
Barker and Schlundt.....	717
Carrier engineering corporation.....	669
Cathode-Kellner Alkali Co.....	669
Cathodes cylindrical. Georges, (D.).....	404
—Digest of patents relating to.....	348
—Preparation for easy removal of de-aerators. Becker, (D.).....	404
—Woven wire cloth as used in Hargreaves-Bird cell. Hargreaves, (D.).....	458
Caustic soda. See also Sodium chloride electrolysis.....	
Caustic soda. Pacific coast enters the field. Great Western Electrochemical Co.....	177
Caustic soda from Western alkali lakes.....	328
Celite.....	259
Cell. Electrolytic. See also under Caustic Soda and various other products.....	
Cell. Electrolytic. Peyrasson, (D.).....	232
Cellulose. From kelp. Glaze.....	355
Cement. High temperature for furnaces.....	714
Quiley.....	717
Cements. See also under Caustic Soda.....	
Central Scientific Co.....	459
Centrifugal force applied to suspensions and emulsions. Ayres.....	500
Centrifugal pump. Adjustable pressure.....	172
Cerium. Use in alkaline storage battery. Edison, (P.).....	283
Chain Belt Company.....	269
Chain vernier and balance.....	230
Chalmers & Williams Co.....	113
Chamber of Mines and Oil of Los Angeles Chart. Nomographic. Bailey.....	595
Chase, Chas. A.....	115
Chattanooga. Industrial developments.....	167
Chemelectric Company.....	670
Chemical Construction Co.....	668
Chemical Refinery, Ltd.....	347
Chemists and the Barber.....	174
Chemist on the board. Hendrick.....	238
Chemists' Club. Announcement of annual meeting.....	554
Chemists' Clubs. School of.....	668
Chemistry. Pure and applied.....	317
Chicago Pneumatic Tool Co.....	613
Chile Exploration Co.....	278
Chile. Nitrate industry. Cuevas.....	426
Chlorates.....	512
Chlorates and perchlorates. Process of manufacture. Gibbs, (P.).....	540
Chloridizing complex ores. Titus and Barescheer, (P.).....	451
Chlorine.....	
—Apparatus for conducting away from cell. Waite, (D.).....	169
—Diaphragm for chloride electrolysis. Clemm, (P.).....	101
—Liquid. Ornstein.....	215
—Uses of chlorine.....	511
Chromic iron ore production.....	613
Churchill Milling Company.....	14
Citizens Gas Company.....	346
Clapp, F. G.....	402
Clarke, T. C.....	553
Clarke, W. H. C.....	670
Classifier. Combined hydraulic and mechanical. Sohlein, (S.).....	538
Classifying. Worr.....	95
Classifying. Dorr.....	295
Claupe process of liquefying air.....	312
Clay. Aluminum from. Meller, (P.).....	221
Clay. Relation to ore-dressing and cyanidation. Allen.....	245
Cleaning metals, (D.).....	555
Clemens, George S.....	115
Clevenger, G. H.....	115
COAL:	
—Chemistry in the coal mining industry. Chance.....	440
—Coal-gas residuals and their application. Wagner.....	493
—Efficiency in blast furnace operation. Burman.....	137
—Grades permissible for reverberatory smelting. Kuzell, (S.).....	338
—In United States.....	14

COAL: (Continued.)	
—Mining in Illinois.....	114
—Refining.....	407
Coal-tar products.....	
—Development in United States. Jordan.....	144
—Production rate. American.....	612
—Statistics.....	496
Cobalt. Separation from ores. McCanna, (F.).....	712
Use in thermocouples. Kowalek.....	477
COKE:	
—By-product plants.....	553, 554
—By-product coke oven plant of Indiana Coke & Gas Co.....	32
—Efficiency in blast furnace operation. Burman.....	137
—From coal-gas manufacture. Wagner.....	493
—Ovens as gas producers.....	407
—Present status of American product industry.....	502, 601
—Reducing agent in electric furnace. Gostrow.....	691
—Sulphur content.....	710
Colé, A.....	234
College of the City of New York. Special lectures.....	250
Colley, B. T.....	458
Colloids.....	215
Colloidal catenism.....	215
Colon. Manganese ore from.....	347
Colorado. Industrial conditions improved. Colorado School of Mines. Co-operation with Bureau of Mines.....	241
Colorado Scientific Society investigates. Everson patents.....	13
Columbia River power.....	408
Columbia University. Engineering research.....	242
Combustion Engineering Corporation.....	612
Complex ore. What is the true value? Plumb.....	8
CONCENTRATION. (See also Flotation.)	
—Central mill of North Star Mines Co. Palmer.....	35
—Classifying. Dorr.....	295
—Combined hydraulic and mechanical classifier. Sohlein, (S.).....	538
—Glass surfaces for ore-dressing. Trewartha-James, (S.).....	398
—Grading industries. Wiard.....	575
—Mass screening with flat screens. Wiard.....	383
—Molybdenite. Andrews, (S.).....	454
—Probability and chance in screening. Herz.....	297
—Relation of clay to ore-dressing and cyanidation.....	245
Conductors for supplying current of electrolytic cells. Leith, (D.).....	170
Congress. Defeat of Lodge dyestuff tariff amendment.....	403
Conigait, Mining, Ltd.....	247
Conifer leaf oil industry. Schorger.....	515
Connorsville Blower Co. Boston type blower.....	584
Consolidated American Smelter.....	624
Consolidated Mining & Smelting Co. of Canada, Ltd.....	243, 613
Contact potentials. Relation between and operation of a copper smelter.....	481
Continuous operation. Value of in ore-testing.....	292
Controllers. Rope operated for small cranes and hoists.....	290
Convention. Northwest Mining.....	347
Cooler. Baker type.....	166
Cooling roasted ore. Hubbard, (P.).....	165
Co-operation in industrial research. Addicks and Lidbury.....	476
COPPER:	
—Allotropy of. Burgess and Kellberg, (S.).....	709
—Arizona production.....	114
—Arizona strike ended.....	124
—Braden Copper Co. practice. Douglass and Colley, (S.).....	279
—Brittleness of annealed copper. Ruder.....	477
—Continuous operation of engine driven generators at Raritan Copper Works.....	244
—Cost accounting in the construction and operation of a copper smelter. Thum.....	525, 573, 660
—Deposition in electrolytic baths. Blum, Haller, Rawdon and Lasier.....	487
—Electric smelting in New Foundland.....	553
—Electrolysis of copper leaching solutions. Greenawalt, (P.).....	609
—Electrolysis with revolving electrodes. Greenawalt, (P.).....	103
—Electrolytic determination in copper manganese.....	441
—Electrolytic refining. Cathode starting sheets. Guggenheim, (P.).....	165
—Electroplating. Babcock and Hagmaier, (P.).....	665
—Feeding blast furnaces in pyritic smelting. Sticht, (S.).....	537
—Grades of coal permissible for reverberatory smelting. Kuzell, (S.).....	338

- (COPPER) (Continued.)
- Hydrometallurgy—
 Nju leaching tests. Morse and Toubertan 332
 Aluminium sulphate solutions as leaching agents. Erdos. (P.) 610
 Continuous leaching apparatus. Golbe. (P.) 103
 Goodrich. (P.) 341
 Leaching at Chuquicamata, Chile. Rose. (S.) 278
 Leaching process. Greenaway. (P.) 610
 Precipitating apparatus for copper sulphate solutions. Irving. (P.) 610
 Melting and refining in basic lined furnace. Addicks and Brower. (P.) 103
 Metallurgy of in 1915 4
 Present conditions and outlook in the West. Ricketts 608
 Production in 1915 623
 Pyritic smelting. The role of sulphur. Sticht. (S.) 223
 Rankin nitric acid process. Rankin. (P.) 103
 Recovery from tailings. Mwater. (P.) 452
 Smelting:
 Consolidated Arizona Smelting Co. 33
 Pyritic smelting at Mt. Lyell. Sticht. (S.) 54
 Finely divided ores. Klepinger, Krejci and Kuzel. (P.) 397
 Starting sheets for electrolytic refining. Elliott and Keshner (D.) 458
 McCoy. (D.) 458
 Vat for leaching or electrolysis. Stout. (S.) 610
 Welding copper with steel or iron. "Copperweld" 552
 Copper Clad Steel Co. 552
 Forwarding instructions. 347
 Cornell University's chemical department burned 290
 Corrosion and the engineer. Walker 382
 Condenser tubes. Institute of Metals report 566
 Discussion 390
 Faraday Society meeting 412
 Influence of alternating current on. McCollum and Ashburn 389
 Meeting of A. I. E. E. and A. E. S. 300
 Cost accounting 462
 Cost accounting in the construction and operation of a copper smelter. Thum 525, 573, 660
 Cottrell, F. G. 170
 Coward, Herbert 234
 Cox shaking screen 386
 Crane. Misjudging the capacity. Rupert 66
 Crucibles. Graphite. Present situation. Crucibles. Proper use 287
 Crushing and grinding:
 Ball-mill development 285
 Dumb bell tube mill. Robertson. (S.) 224
 Grading industries. Wiard 575
 S. 191, 383, 529, 292
 Need of ball-milling data 230
 Symons disc crusher 346
 Cunningham, F. W. 229
 Cutler-Flammer Clutch Co., lifting magnets Cut-out. S & H special 167
 Cyanamid:
 Landis 513
 Norwegian power used 513
 Production of ammonia from. Landis 87
 Cyanide process. See Gold and silver.
 Cyanides or cyanamide. Electric furnace. Bucher. (P.) 543
 Cyanides. Manufacture. Acker. (P.) 57
 Cyanides. Manufacture. Ashcroft. (P.) 57
 Cyanogen. From coal gas manufacture 494

American Chemical Industry in 1915

Heraclitus, the "dark" Greek philosopher, was born some twenty-five centuries too early for the full appreciation of the fundamental idea of his doctrine: $\pi\alpha\upsilon\sigma\iota\varsigma$ $\rho\epsilon\iota$. Instead of *being*, the sole actuality is *becoming* or eternal flux and change. Harmony and unity consist in diversity and multiplicity. How Heraclitus would have been charmed by the principle of relativity in modern physics. But his greatest delight would have been modern chemistry which while dogmatizing the permanence of matter, discloses matter in its frailest and most fleeting forms of existence and reveals perpetual transitory reactions where the unskilled eye sees a dull equilibrium.

The chemical industries in America to-day reflect the transient character of chemical reactions. It would be just as ridiculous to try and say what the American chemical industries *are* at this New Year's day, as to take a single instantaneous picture out of a moving-picture show and make believe that it tells the story. And all the charm would be lost which comes from the realization of the fact that we are witnesses of chemical history in the making—nay more, strong-willed enthusiastic actors and creators.

Creators, just as Luther Burbank is a creator when he grows a spineless cactus and works other marvels in plants, fruits, and flowers. For industries grow as living organisms like plants and trees. To a greater degree than plants or trees can they be shaped by the will of man, yet they always remain children of the soil. Without the natural resources, without the markets, without transportation facilities, without labor of such psychological make-up as to adapt itself to the task in hand, the most powerful will of man is powerless. Such fundamental considerations have directed the evolution of the American chemical industries, so that this country has become the largest producer of sulphuric acid, that manufacture of cellulose and wood-distillation have made great advances, and that its splendid electrochemical industries have been created of unique scope and individuality.

When the European war cut off imports and opened to American manufacturers new and clamorous markets, the whole industrial system was upset, as though a very high tariff had been enacted over night, and a fever of activity started. And here the free creative will of the American chemist came in powerfully. The American chemist saw his duty and did it there and then. He did what was humanly possible and almost more. Our readers know how the dye problem was attacked and the potash problem, how new chemical industries were started and how the old established ones readjusted themselves to changed conditions and are

straining every nerve in incessant work day and night. Look at Niagara Falls, how the electrochemical industries have been affected almost without war orders. Our Niagara friends have only one thing to worry them—the power famine. *Quousque tandem?*

While a snap shot of all this activity would be flashy enough, it would not show tendencies. We believe evolutionary sketches of different branches of chemical activity to be published during the present year will be more welcome and more useful. We begin in this issue with a sketch of the rubber industry, which, we trust, will be found very interesting, and we also publish in full Mr. Maximilian Toch's paper on the new American barium industry, though we abstracted it quite fully right after it was presented, in our issue of Oct. 15, 1915 (page 710). Mr. Toch's paper brings out clearly and strongly one all-important point. This is a glorious but a critical period in the evolution of American chemical industries. Shall they grow? Have they been built to stay? The American chemical industry is a child of the American soil. It is part of the whole industrial organism of this country. It asks the American nation for a fair attitude of mind. It needs its intelligent support, as Mr. Toch's paper states it in detail. That it may get it, let this be our New Year's greeting to the chemical industry.

Flotation in 1915

The air has been full of flotation—and appropriately so. American metallurgists seize on any idea that promises success, and work it to the limit. A year ago copper leaching held the stage. This year it has been flotation. A year hence we can look for zinc leaching with electrolytic deposition.

Some excellent theoretical work has been done on slime in an endeavor to explain the phenomena of flotation in terms that will be acceptable to the physicist. We are now doubtful whether surface tension will completely explain it, for the exponents of an electrostatic theory, based on well known principles of colloid chemistry, are at least making us feel that their work cannot be left out of account.

A peculiar situation has developed in the wood-distilling industry as a result of the expansion of flotation during the year. For years past, pine oil has been more or less a burden on the hands of the wood distillers, as there was little market for it. Further, due to the demoralization of this industry from other causes, turpentine has been selling for several years at a cost considerably below 50 cents per gallon. And since most of the wood-distilling plants in the south had been constructed on the expectation of selling turpentine for at least 50 cents, many of them have been obliged to close. As a consequence, most of the immediately available supply of pine oil, which has accumulated for years, as well as most of the other wood-distillation products, have been consumed. Rosin, rosin oil, pine tar, pine-tar oil, wood creosote, and even crude pyroligenous acid are acceptable for flotation, so that wood distillers are now looking toward the metallurgical industry for salvation. This is only another example of

an unrelated industry receiving an impetus from unexpected metallurgical development.

On the other hand, with the price of pine and other wood oils soaring, flotation men have been turning to cheaper oils. Coal tar and fractions from the distillation of coal have been meeting with favor, the coal creosotes especially being in demand. Gas works and by-product coke works are finding markets of no small proportions for some of their products, and it is only a question of time till the treatment of these by-products from the distillation of coal will be adjusted according to the needs of the metallurgical industry, as was the production of coke. Further, petroleum producers have been wanting to get into the flotation field, but most of the petroleum products have not met with success unless mixed with a small proportion of one of the wood oils or some of the coal-tar products. Here the importance of Rittman's inventions for treating petroleum for the production of aromatic hydrocarbons may prove of importance in preparing flotation oils.

In the face of all this work with oil, comes one Louis A. Wood, of the Minerals Separation Company, with a frothing process in which no oil is used, and in which air bubbles alone do the lifting. It is yet too early to say what the effect of this invention will be, as the process is said to be a delicate one and may not succeed well enough to be applied in practice.

Oils are now being classed as "collectors" and "frothers." Coal-tar products attach themselves well to the minerals desired and are examples of collectors. Pine oil products froth well and make a desirable addition to the coal-tar products in order to get froths of varying consistency and depth. This is especially desirable in the treatment of lean ores. Other addition agents are legion. Thiosulphates and sulphites "deadened" the minerals toward flotation and are used in limited amounts for purposes of differential flotation. In the same class comes the use of bichromates for deadening galena, and permanganates for deadening zinc sulphide. Substitutes for acid are numerous, and include sodium bisulphate, any fluosilicate, aluminium sulphate, organic electrolytes such as tartrates, citrates or citric acid. In fact, many mills have now come to the use of almost no acid, or even to an alkaline electrolyte. The latter seems specially adapted to the treatment of pyrite and related minerals as well as to partly oxidized dump residues.

During the year has come the announcement that it is possible to float certain gold and silver ores in such a manner as to either displace or supplement cyanidation. Unfortunately it has not been possible to float in a cyanide solution. The importance of this development is hard to estimate, but already it is evident that it will be possible to concentrate ores containing an excess of cyanicides and obtain an enriched product that can stand the expense of special treatment which will remove the cyanicides or render them of no effect. In many instances flotation concentrates will be sent to the smelters instead of being cyanided, but in isolated places it will doubtless be best to cyanide the concentrates and thus avoid freight charges.

We have been informed that there seems to be some chance of applying flotation to the native copper ores of the Lake Superior district. This will be a step that has been needed for the recovery of fine copper which has hitherto escaped mills of the old type.

One of the most notable effects of the introduction of flotation has been the simplification of concentrator flow-sheets. This is especially noticeable in the larger copper concentrators, where the necessity of stage grinding is not so pressing as it was when we were trying to slime a minimum amount of the valuable minerals. The coincident development of roughing tables has also contributed to simplification; and now we have the phenomenon of the Anaconda company raising its extraction from 78 per cent to over 90 per cent, and doing this with a simplified mill.

The flow-sheets of the flotation sections of mills also have been undergoing standardization. As an example, the Callow cells are being used largely in sets of two cells in tandem, the first being used as a rougher and the second as a cleaner of the low-grade concentrate of the first. The middling product from the second is returned to the feed of the first. The mechanically agitated, or Minerals Separation, type of flow-sheet is of two kinds. First we have installations in which a set of from three to sixteen roughing cells produces a concentrate to be sent to a set of cleaner cells, the middling from the latter being returned to the feed of the former. The other type uses from six to sixteen cells in series, the froth from the first two, three or four being finished concentrate, while the froth from the remaining cells is returned to the feed. By this method the grade of both feed and concentrate is considerably raised. For the past few months the grade of concentrate from Butte & Superior has been 56 per cent zinc instead of 51 per cent to 53 per cent, and we understand that this is due to the adoption of a flow-sheet including roughers, cleaners and re-cleaners.

Since the development of pneumatic flotation a number of "subaeration" machines have been devised, particularly by the engineers of the Minerals Separation company. A jet of compressed air is introduced under the impellers in each cell, and this air is beaten into the pulp. This type of machine has proved very efficient, especially as a rougher. Furthermore, in this way it is possible to control aeration to any extent, making possible the application of differential flotation to mixed sulphide ores.

The present question is, What is the future of flotation? Some have been inclined to decry the importance of the process, claiming that it will not prove a panacea for the concentration of all low-grade and complex ores; but they lack caution, for we have not yet seen the end of the development along these lines. As we are only beginning to lose our fear of slime in concentrating processes, we must wait until we can see the logical result of this confidence in our ability to treat some of the most difficult products that have confronted the millman. A mill which will deliberately slime all of the ore before concentration is still as much of a novelty as were the early all-sliming cyanide mills. Fur-

thermore, we have yet to see what can be done with the complex micro-crystalline sulphides through the application of differential flotation. And lastly we have encouraging reports as to the possibility of floating carbonates of lead and copper. At least three mills are investigating this work on a large scale, using soluble sulphides to film the carbonate particles so that they can be floated.

A campaign of research and testing is on at nearly all of the larger metallurgical plants, as well as in the laboratories of ore-testing companies, consulting engineers, universities and mining schools, from all of which much good must come. We must wait a little longer before we can define the field to which flotation processes will be limited.

Precious Metal Metallurgy in 1915

A review of the past year's progress in the metallurgy of gold may well begin, as all reviews of the metallurgical year should begin, with consideration of the advance of concentration by flotation. Promising to be as epoch-making as was the development of cyanidation, its future position in gold metallurgy is perhaps not so clearly defined as its field in competition solely with gravity concentration processes: for instance, in the dressing of lead, zinc and copper ores. How far it may encroach upon the territory of amalgamation and of cyanidation is problematical, but doubtless it will in great measure determine the future trend of developments in these branches of the art. Seemingly there should be no difficulty in the flotation of amalgamable gold, and in the many instances where sulphide or telluride minerals are the carriers of the precious metals the new process may offer an economical method of either accomplishing a satisfactorily complete extraction in a single operation or of permitting secondary treatment to be confined to a small enriched fraction of the original ore, with resultant saving in plant construction and operation.

In the latter connection Mr. Butters notes difficulty in cyaniding the concentrates produced by flotation methods, particularly those containing gold and silver, and we feel that this difficulty must be surmounted before the process can win the recognition it undoubtedly merits, since the cost of marketing a concentrate would often detract from the economic success of the process. Mr. Butters' further statement that he is working in alkaline solutions, despite the early belief that the presence of acid was of prime necessity, is of more than usual interest. The effort to avoid the many practical difficulties certain to be encountered in the handling of acid solutions is well worth while and the incident illustrates anew the value of the skilled operator's experience in the organization of such experimental work.

The public has but insufficient data of flotation costs: we know of none that does not exceed the low point recorded by many mills using cyanide, so that here the newer process cannot enter except to rectify faulty extractions. However great the promise of flotation, it will not fully redeem this promise until the courts finally pass upon the ownership of the underlying patents.

Alaskan developments have reached consummation during the year and our information is to the effect that Mr. Jackling's application of copper-milling methods has been justified by results. Rolls are not to be the only machine to challenge the long maintained supremacy of the stamp mill, for the ball mill, employed years ago in Australia, is finding successful application in the same field. In the large installations of the present day the stamp mill, an inherently cumbersome machine, is at a disadvantage both as to first cost and operating cost. It is said that as compared with the ball mill it requires nearly double the mill space for equal crushing capacity and that the cost of installation is about in the same ratio. The rolls at Thane have also made splendid records, and perhaps the old machine is in greater danger of being supplanted than it ever has been before. As further invasions of its territory occur, amalgamation may simultaneously lose more ground as a primary process, since the stamp is peculiarly favored as an amalgamating device, providing at once admirable mixing of quicksilver and ore and freedom from undue "flouring" of quicksilver.

Nevertheless, such widely separated installations as the Nipissing high-grade mill and the Thane treatment of concentrates suggest that, in modified form of application, amalgamation will continue a useful tool in the hands of the well-equipped metallurgist.

Perhaps the most striking feature of all recent designing is the simplicity of the modern flow-sheet. Whether the process be crushing and concentration, as at Alaska, amalgamation and cyaniding as at the Homestake, or crushing in cyanide solution with "all sliming" as at the Hollinger and other plants, the processes and equipment are being stripped one by one of their nonessentials; and costs, responding to this analysis, are falling to levels but recently thought to be unattainable. The incomplete data available on flotation suggest that a similar winnowing is in progress here, as we note that many of the steps which Hoover's treatise deemed essentials are either being questioned or discarded. We have already alluded to Mr. Butters' efforts to avoid the use of acid; similarly the use of heat is no longer of universal application.

In cyanidation, the year has brought us little that is novel. Probably the further development of continuous counter-current decantation is the most notable feature. Patent litigation may have had its influence in hastening this development, but the process has so much to recommend it that even without the necessity of considering the question of royalties it is doubtful if filtration could in turn drive out its successor.

Several metallurgists, in discussing certain aspects of the cyanide process, have agreed that precipitation methods offer more promise of reward for the investigator than do any other phases of the process. It may be inferred, therefore, that careful study is being given to this branch of the art; yet despite this consideration and despite the abnormal prices which have prevailed in the spelter market during the past year, no developments are recorded. Zinc is still the foremost precipitant, with the dust more generally used than the shav-

ings. Aluminium powder has a limited use. The electrolytic, sodium-amalgam and charcoal methods are not in evidence, although the first two of these are, in theory, most inviting. In a characteristically thorough paper, Professor Clevenger has reviewed and discussed electrolytic methods of precipitation.

In the laboratory we note the advent of a dependable mechanical sifting device which eliminates the personal equation and the fatigue from screen analysis. A 300-mesh sieve has also been placed on the market. Both are useful additions to equipment, for we know of nothing so informative as well made gradings of the ore in various stages of treatment, and means of facilitating such inquiries have long been needed. The 300-mesh sieve has enabled us to amend somewhat our practical definition of "slime" by withdrawing a portion of the former finest product, the minus 200-mesh material, from this classification. Slime remains the unmeasurable, the "over yonder," material.

That Vesuvius of metallurgical journalism, the discussion of the law of crushing, has been quiescent during the greater part of the year except for occasional rumblings and minor flows of equations. Quite recently, however, a tremendous eruption from the foremost Kick partisan has reminded us that now, even as in the days of the Society upon the Stanislaus, the consideration of such subjects is fraught with danger. Nevertheless, we are confident that we shall hear more of it during the coming year.

Copper Metallurgy in 1915

The past year's progress in the metallurgy of copper has been along the lines discussed in our review of a year ago. At the beginning of the European war so much uncertainty existed as to the market for copper, that production by leading companies was greatly curtailed and the price of copper dropped to a low figure. This condition continued only a short time, however, for there soon came a heavy foreign demand which resulted in a recovery in price and unusual activity among copper producers. This condition is likely to continue at least until the end of the war, and possibly for some time thereafter.

The outstanding feature of the year was the general adoption of flotation, which had the effect of discouraging experimental work in hydrometallurgy, particularly where preliminary roasting of sulphides was involved. In some cases, plans already under way for copper leaching were wholly abandoned or modified in a marked degree. The result is that developments in the hydrometallurgy of copper have not shown the strides that were so confidently predicted twelve months ago. It is true that leaching is still attractive for the treatment of certain oxidized ores, and we will hear more of this work when the extreme popularity of flotation wanes. The process of Weidlein, previously mentioned in our columns, is under experimental operation, and apparently offers promise of successful development.

Flotation has found its greatest economic use in the recovery of finely divided mineral. Where the copper

minerals occur in small particles finely disseminated through the gangue, necessitating fine grinding for their liberation, or where friable copper minerals occur with other less friable sulphides, flotation is admirably adapted as a process of concentration. If, in addition, oxidized minerals accompany the sulphides, the former also may be floated after treatment with a soluble alkaline sulphide, coating or filming the particles with copper sulphide. This effects a greatly enhanced saving. Past losses in concentrating have amounted to as much as 30 and 40 per cent, due mainly to an excessive loss of the finely divided mineral; but this will be largely overcome by the use of flotation which yields a high percentage recovery on slime. The process also seems admirably adapted to the treatment of the "porphyry" ores as an initial step.

On the other hand, ores like those of the Butte district, which yield good products with jig and table concentration, require flotation simply as an auxiliary step after the use of the older standard methods. At the same time, having lost the fear of being unable to make a satisfactory recovery on slime, the upper limit of size for jigging has been greatly reduced, with the result of a greater total recovery of metal through the use of flotation. Tailing formerly carrying from 0.5 to 1 per cent copper may now be reduced to about 0.1 per cent.

The production of fine flotation concentrates has had the further effect of necessitating a greater extension of reverberatory smelting. Agglomerating methods applied to fine copper mineral to fit it for blast-furnace smelting have not been extensively applied, and it is fair to assume that by far the major portion of all fine concentrates will in the future be smelted in reverberatory furnaces.

The new furnaces, as previously noted, are much larger than the earlier types, and will permit a continuous flow of slag. The new method of charging along the full length of the side walls also renders unnecessary the frequent fettling called for under former practice, because the charge banked up against these walls affords a protection from slag corrosion.

The present tendency is toward coal-dust or oil firing of reverberatory furnaces, depending on the location of the plant with respect to fuel supply. In some localities coal of any grade is expensive while oil is relatively cheap, and under such conditions it is doubtful if coal-dust firing can find favor. Excellent fuel ratios are obtained under either system. Other advantages are found in an increased tonnage; maintenance of a higher temperature; requirement of less draft than with ordinary grate firing.

The requirements for oil-firing are comparatively simple. The oil is preheated to a temperature ranging from 160 deg. Fahr. to 200 deg. Fahr. at different plants, and is fed under a static pressure of from 35 to 40 lb. In the burners the oil is atomized by air at 40-oz. pressure.

Coal-dust firing is not new in its inception, but early trials were failures because many of the features essential to success were not understood. These features

are: drying the coal to 1 per cent or less moisture; fine pulverization, so that 93 to 97 per cent will pass 100-mesh, and 82 per cent is finer than 200-mesh; proper proportioning of fuel and air; use of fuel with 20 to 30 per cent or more volatile matter; correct design of the furnace and provision for taking care of the ash formed.

While blast furnaces are being discarded in certain plants, they are indispensable where low-grade high-sulphur ores are available, as at Mt. Lyell, Tasmania, and where pyritic or semi-pyritic smelting can be practised they bid fair to remain in use as long as suitable ores can be found.

In the realm of crushing and grinding for concentration there has been a steady development of ball mills of various types. The principle feature of their construction is a lowering of the point of discharge as compared with that of feed. In some case this is accomplished by means of lifting devices in the discharge end, while the extreme suggestion is for the use of an open-end discharge. Disk crushers and grinders also have been receiving favorable consideration for both coarse and fine work. These machines offer the advantage of giving a true crushing action without grinding by abrasion also, and for certain purposes this effect should be valuable.

The Year in Zinc Metallurgy

The logical sequence of the unusually high price for spelter during 1915 was a stimulus, not only to ordinary retort smelting but to the development of other methods of reduction and the utilization of low-grade ores. Smelting plants which had been abandoned for years were rehabilitated, and some new construction was completed. The Donora plant of the United States Steel Corporation was brought into production in the record time of four months and ten days from the time of beginning construction, or in about one-fourth the normal time for the construction of such a plant. An unusual feature of this smelter is the extensive use of concrete in its construction.

The Joplin district profited tremendously from the high prices which prevailed, and the construction of new concentrating plants has exceeded any previous record. The later plants are of good design and should effect a higher saving, particularly on slime, than has been customary in the older mills.

In the field of dry concentration and separation, there have been no new developments beyond the standard electrostatic and electromagnetic machines and the Plumb pneumatic jig, all of which are now well known.

During a year which gave promise of definite results from electrothermic smelting, there was little or nothing forthcoming, and at the time of writing much more interest centers in electrolytic zinc. The present position of these two processes is quite reversed from that of a year or two ago. At that time electrolytic methods were not received with much favor by some of the largest zinc-producing concerns on account of the high capital cost for plant, whereas electrothermic smelting was conceded to be promising for the treatment of

mixed sulphide ores of zinc, copper and lead. To-day, although electrothermic reduction still holds its possibilities, it is not as near commercial reality as is the other process. Some of our largest and most progressive metallurgical organizations have undertaken the leaching of zinc ores, with electrolytic deposition, and have experimental plants under operation. The article by D. A. Lyon, O. C. Ralston and J. F. Cullen on hydrometallurgy of zinc and lead in 1915, published elsewhere in this issue, will be found particularly interesting in this connection.

The zinc oxide plant at Leadville, already described in this journal, has afforded an outlet for a small tonnage of low-grade carbonate ore. The product has been in steady demand, finding its way into the chemical trade.

Calcination of zinc carbonate ore for the purpose of enriching it by expulsion of carbon dioxide is not as extensively practised in this country as in Mexico. In the latter country the process has been perfected to a satisfactory point and is in operation at several places. In the United States the only calcining plant of which we have knowledge is that of the Empire Zinc Company, in Nevada. Coarse ore is calcined in a vertical kiln, and the fine in a rotary furnace. The success of the process in Mexico seems to be due to the peculiar form of kiln used and the careful manner in which the charge is fed by hand. For the latter purpose cheap labor is an essential.

Needless to say, flotation has played a conspicuous part in the concentration of zinc ores, greatly increasing the recovery. Experimental work on the flotation of carbonate ores is proceeding, with better prospect of success than could be reported a year ago. Just how much zinc has been added to our total output as a result of flotation is difficult to estimate, as the use of the process has so modified the previous milling practice that the mineral actually recovered by flotation is probably much more than that which was counted a loss in former practice, and which flotation was first expected to save. In any event, the total must represent an appreciable percentage of our total production.

Chloridizing and other special processes have been quiescent during the year, but their exponents are still active and promise developments in the near future. At the present time active experimentation is a negative quantity.

The Steel Trade's Wonderful Year

To reach a correct conception of the influence responsible for the remarkable showing made by the American steel industry in 1915, its change from a rate of operation less than 35 per cent of its capacity to a rate of operating under the highest pressure it ever knew, the most direct method seems to be first to analyze the character of the demand at the close of the year, to consider the precise position attained before endeavoring to trace the steps. One reason for adopting this course is that during the year the impression arose that steel activity was due in large part to orders for "war steel" and while that view may have been substantially correct at one

time it was not correct as to conditions in the late months of the year. If the influence of orders for war steel is rated too highly, the easiest method of correcting the misapprehension is to consider conditions in the steel market at the close of the year.

Steel, of course, is involved in two classes of exports, the steel exported directly from the mills and reported by weight in the government's export statistics, and the steel which passes to various manufacturers and is converted into merchandise that is exported. The iron and steel exports returned by weight increased steadily during the year until August, when they reached a maximum of 406,000 gross tons. There was a decline to 382,000 tons in September and a further decline to 351,000 tons in October. Excluding from the October returns pig iron, scrap, iron castings, etc., there was about 300,000 tons of finished steel, representing a rate of 3,600,000 tons per annum. Steel production increased from August to October, so that the percentage of steel exported decreased very materially. Steel shipped by mills for indirect export can be estimated only very roughly. It includes steel for shells, arms, locomotives, freight cars, automobiles, machinery, etc., but an estimate of 300,000 tons a month seems high. If we assume that the total steel made in October for export, direct and indirect, was at the rate of 7,000,000 tons a year, it represented no more than 25 per cent of the production, which may safely be estimated at about 28,000,000 tons a year, in terms of finished rolled steel. The remainder passed into purely domestic use. In November a serious freight congestion began to develop between mills and tidewater, resulting early in December in the railroads placing embargoes on shipments of steel intended for export. Shipments of the mills for export were thereby reduced, while shipments to the domestic trade were correspondingly increased, and yet the domestic trade was not glutted, but called for more steel. Thus the condition at the close of the year was that steel-mill shipments represented something like 80 per cent domestic and 20 per cent export, direct and indirect. A portion of the export material, furthermore, was not war material.

The domestic steel-consuming trade had thus become a very large buyer. There were two chief causes for the remarkable improvement that occurred during the calendar year 1915, one being that in the closing months of 1914 industry had passed far below normal and could not but react, the other being that the tremendous export trade of the country was making it prosperous. The war produced a mental panic, which reached its worst stage perhaps at the close of October, 1914. There would have been more than a mental panic if the stock exchanges had not been closed and the new banking system had not been scheduled to go into effect on Nov. 16. While industry was generally depressed, the buying of steel reached a lower ebb than corresponded to the amount of industrial activity, because jobbers and manufacturing consumers reduced their stocks. In our review of a year ago, explaining the extreme depth of depression to which the steel trade had fallen, it was pointed out that fluctuations in steel production were

due in considerable part to the fact that in this industry the buyer rather than the seller carries stocks.

In December, 1914, a moderate amount of steel business was booked, at prices which averaged, for the various finished products, a somewhat lower level than that which obtained in November, 1911, and were therefore the lowest in more than 15 years. The mills were operating at less than 35 per cent of capacity. The business booked was chiefly for January and February shipment. The mills then succeeded in mustering sufficient courage to advance bars, plates and shapes from 1.05c. to 1.10c. on Jan. 1, a proceeding which gave some encouragement to the trade at large. By very easy stages other price advances were made during the half year. It was recognized that the preceeding was somewhat unusual, for the history of American steel markets in general shows that prices have no inherent strength, or at least advancing tendency, unless the mills are operating at about 85 per cent of their full capacity.

A remarkable part was played by "war orders" for steel during the second quarter of the year. While such orders had been placed at intervals the bearing upon the market as a whole had not seemed important. In April reports were circulated of very large tonnages of shrapnel rounds being sought, both for direct export and for shell manufacture in the United States. In many quarters these reports were not taken very seriously. Secrecy surrounded the placing of many of the orders, but in the course of a few weeks domestic buyers of steel came to realize that the war business really was important. In May and June orders were placed for fully 50,000 freight cars, about one-third being for export, these orders being more than double the total placed in the nine months from the inception of the war up to that time. The fear that the war demand for steel might make steel scarce in the United States, the encouragement given by the resumption of railroad buying, and some minor influences, gave a very decided stimulus to steel demand in general. Steel mills operated at close to 85 per cent of capacity in July and in August they reached substantially full operation. Deliveries began to fall behind and buyers then took hold with vigor.

Steel prices, which advanced rather haltingly during the first half of the year, and then only by an average of about \$2 a ton, began to advance more rapidly, and in October an unprecedented rate of advance was developed. Steel prices rose during the last three months of the year at an unprecedented rate, barring only the altogether exceptional advance of 1899.

The mere volume of demand was not sufficient to account for the exceptionally rapid advance in these three months. There was an abandonment of the policy pursued by steel manufacturers in various other periods of heavy demand, that of holding prices down to what was regarded as a fair normal level. The decision rendered June 3, 1915, in the case of the Federal government against the United States Steel Corporation had given the corporation itself a clean bill of health, while it had roundly condemned the "Gary dinners." The steel makers felt that they were perfectly free to allow prices to advance indefinitely, if they tended to do so; that as

they were denied the privilege of holding them up to what they considered a normal level, in times of poor demand, there was no occasion to hold them down to such a normal level in times of good demand. There was the further influence that the demand for steel was regarded as largely a creature of the war, that a termination of the war might greatly reduce the demand. The advances in finished steel prices during the second half of the year averaged about \$11 per ton, making about \$13 advance for the whole year. The advance could be regarded as still greater if account were taken of the premiums paid for prompt deliveries in the case of some products. The level at the close of the year was a trifle above the top point reached in 1907 and therefore represented the highest level since 1902. Prices were about \$6 a ton above the top reached in the 1912 movement and about \$4 a ton above the highest level reached in the movement of 1909.

As already indicated there was a decided increase in domestic buying in the mid months of the year, due in considerable part to sentimental influences. Such buying would in the course of months play out; buyers would become stocked with material, but no such playing out has occurred. No stocks to speak of seem to have been accumulated; on the contrary many buyers are clamoring for better deliveries. The actual consumption of steel has evidently greatly increased.

For many decades, through the year 1907, the demand for iron doubled on an average once in each ten years, though far from regularly year by year. It becomes impossible to judge at any time what is the normal demand, to determine whether a given demand being then experienced is normal, below normal, or above normal. There was a period of twelve consecutive months ending October, 1907, in which the production of pig iron was 27,000,000 tons. The existing capacity, eight years later, is 38,000,000 tons or thereabouts, representing a considerably smaller increase than would be represented by a doubling in ten years. A demand that fully engages the existing capacity may not be an abnormally heavy demand at all. It is a fact that a considerable number of the steel consuming industries are but indifferently employed. The demand for structural steel, for instance, has been conspicuously light.

Perhaps it is no great measure of prosperity in the consuming trades that has made the steel industry itself so prosperous. The prosperity of the country at large is traceable to the enormous balance in its merchandise trade. In the twelve consecutive months ended with November the merchandise trade balance in favor of the United States exceeded \$1,700,000,000. For a number of years an apparent favorable balance in merchandise of about \$500,000,000 served to equalize the unseen balance. A balance \$100,000,000 a month greater naturally induces prosperity.

Pig-iron production in the United States was 12,233,791 gross tons in the first half of 1915 and about 17,700,000 tons in the second half, making about 29,900,000 tons for the year. The record calendar year was 1913, with 30,966,152 tons, the record half-year being the first half of 1913, with 16,488,602 tons to its credit.

Nomographic Charts for Conveyor Belt Calculations

To the Editor of Metallurgical & Chemical Engineering:

SIR:—I have studied with much interest the chart for the quick calculation of problems relative to rubber conveyor belts which was published in the Nov. 1, 1915, number of METALLURGICAL & CHEMICAL ENGINEERING. The graphical method of representation is finding new applications every day and Messrs. J. D. Mooney and D. L. Darnell have given us a very good example of the rectangular co-ordinate type of chart. It has appealed to me, however, that the equation in question is admirably suited to another type of graphical solution, namely, the nomographic chart, and with the idea of calling attention to this second graphical method, I have constructed the charts, reproduced on page 9.

Fig. 1 is a nomographic chart for the solution of the same problem as that treated by the aforementioned authors, namely, the determination of the correct number of plies for a rubber conveyor belt operating under certain conditions. The equation represented is given by them as

$$p = KgW(L + 10H)$$

where

p = the correct number of plies.

K = a constant depending on the type of drive. For a simple drive with a bare pulley, it has the value $1/250,000$.

g = the weight in pounds per cubic foot of the material handled.

W = the width of the belt in inches.

L = the length of the belt in feet (approximately twice the center distance).

H = the difference in elevation between the head and tail pulleys in feet.

The nomographic chart consists of three scales and one supporting line BB . On the scale AA is the length factor f equal to $(L + 10H)$, on the scale CC , the width of the belt W and also the weight of the material g , and on the scale DD is the number of plies p . To solve the equation for p , knowing the other variables: Place a straight edge across the chart connecting the points representing W on the scale CC and f on the scale AA ; place a pencil point on the intersection of this line with BB and swing the straight edge till it connects this point with the point on CC representing g ; where this line intersects the DD scale read off the correct value of p .

For example, take the same set of values used to illustrate the rectangular chart, width 36 in., length 300 ft., difference in elevation 20 ft. and material, sand and gravel. The arrow pointed lines show the solution of this problem. Connect a (500 on AA) with c (36 on CC); connect b , the intersection of this line with BB , with c (90 on CC) and note that d on DD falls between 6 and 7 indicating that 7 is the proper number of plies. Note that it is unnecessary to actually draw the lines connecting the points.

The advantages of the nomographic as compared to the rectangular co-ordinate chart are briefly these:

1. It is easy to construct; but few lines are necessary to represent a formula and the calculation is simple.

2. It is easy to read; it does not present a mass of lines to the eye.

3. It is easy to interpolate; interpolation is always easier on a scale than between lines on a plot.

4. The solution is equally simple whichever quantity is the unknown.

5. Any number of variables can be accommodated.

The rectangular chart for the solution of the formula was for but one drive only, and the value obtained by it had to be multiplied by a conversion factor if a calculation for one of the other types of drive was desired. The nomographic chart can be made to accommodate the added variable by merely adding another scale and line. Fig. 2 shows this chart arranged to accommodate the varying K . To solve the same problem as before, connect a (500 on AA) with c (36 on CC); connect b , the intersection of this line with BB , with c' (90 on CC); connect b' , the intersection of this second line with $B'B'$, with a' ($K = 1/250,000$); this line cuts out the correct value of p on DD .

The nomographic chart is especially applicable to exponential and power equations and a study of its utility in this direction is well worth while.

What Is the True Value of a Complex Ore?

To the Editor of Metallurgical & Chemical Engineering:

SIR:—From time to time I have noticed articles by many different engineers and metallurgists on the subject of "Mine Valuation." I do not recall having seen anything in the nature of a discussion of "Ore Valuation." Since my work for the past thirteen years has been almost entirely along the lines of valuation of complex ores, especially those containing zinc, I propose to open a discussion by submitting the following:

Having worked out the treatment of several "complex ores" and having attempted to devise a treatment for several hundred others, I have taken a specific case which has come to my personal attention and which, I believe, will serve the purpose of argument more completely perhaps than a general discussion of the subject.

During the greater part of the present year, owing to the unusual activity in the zinc industry, engineers have had many occasions to examine and report on mines, the values of which depend to some extent on the zinc contents of the ores. The mine is sampled and the ore assayed and measured to a point where the engineer finds a certain number of tons carrying a certain amount of gold, silver, copper, lead, zinc, iron and any other metals that can be recovered and sold. It is at this point in his examination that an understanding of the methods of treatment to be employed that will effect a commercial saving of the metals, the cost of such method and the marketing of the products, is fully as essential to the correctness of his findings as is the knowledge of methods for sampling, assaying and measuring the ore.

It is at this point also that the assayer has found himself in a most embarrassing position; not on account of his inefficiency as an assayer, but because he has not the facts at hand upon which to base a sound opinion as to the value, in dollars and cents, of the ore upon which he has determined the metal contents. I have seen assay certificates from reputable assayers which showed fully the metal contents, and in the space for that purpose was shown a value which had been calculated from the analysis. In many cases these "values" have been found to represent the metal values, based upon the current market quotations for the dif-

CALCULATIONS, CONSTRUCTED

BY R. E. HAYLETT

$$p = kgW(L + 10H)$$

FOR A SIMPLE DRIVE WITH BARE PULLEY

$$K = 1/250,000$$

FIG. B—CHART DRAWN
FOR VARIOUS DRIVES

$K = 1/250,000$ for a simple
drive with bare pulley

$K = 1/300,000$ for a simple drive
with rubber-lagged pulley

$K = 1/375,000$ for a tandem
drive with bare pulleys

$K = 1/450,000$ for a tandem drive
with rubber-lagged pulleys

ferent metals delivered in New York. It is needless to say that this method is misleading and may result in great financial disaster if further investigation is not undertaken.

Many engineers have attempted to estimate such ore values by allowing "liberal" losses. By this method great mistakes may be made chiefly because the losses allowed have not been sufficiently liberal. It is my intention to try to show that there is no possible way by which these losses can be estimated. They must be accurately determined, and in most cases, they will be found to be surprisingly large.

Some months ago I was asked by an engineer who had finished an examination, what percentages of saving could be reasonably expected by the most modern practice. I was told that the ore had a value of \$12 per ton, based on a price of \$20 per ounce for gold, 50 cents for silver, 50 cents per unit for lead, and 60 cents per unit for zinc. He had not assayed for iron since it had little value. I was unable to make an estimate for I did not know, nor did any one know, what grades of products could be made or how much of the gold and silver would be found in the zinc product. These facts, which are absolutely essential, can be determined and must be determined before the value of the ore can be definitely fixed.

To illustrate how difficult it would be to estimate a value of this kind, I submit the following table to show what products can be made and what money will actually be received at a certain stage of the metal market, for a certain ore.

	Wt.	Oz. Au	Oz. Ag	Per Cent Pb	Per Cent Zn	Per Cent Fe	Per Cent SiO ₂
Original ore.....	100	0.07	9.00	8.00	16.00	7.00	46.00
Lead product.....	3	0.32	45.00	68.00	5.00	6.00	2.00
Per cent saved.....		36.50	40.00	68.00	2.50	6.80	0.30
Iron product.....	14	0.22	17.00	8.00	11.00	32.00	6.00
Per cent saved.....		44.60	26.40	14.00	9.50	64.00	1.80
Zinc product.....	26	0.02	6.50	2.60	48.00	5.00	10.00
Per cent saved.....		8.50	19.00	8.60	78.00	18.50	5.60
Silme.....	7	0.04	11.00	7.00	12.00	6.50	49.00
Per cent saved.....		4.00	8.50	6.10	6.20	6.50	7.40
Tailing.....	45	0.01	1.20	0.60	1.70	0.70	86.00
Per cent lost.....		6.40	6.00	3.30	4.70	4.20	84.90

It will be seen that the total concentrate carries 89.6 per cent of the gold, 85.5 per cent of the silver, 90.8 per cent of the lead and 90.1 per cent of the zinc. This can certainly be called a high saving.

The original ore has a value of \$29.10, estimated upon metal contents and quotations, with gold at \$20 per ounce, silver at 50 cents, lead at 4½ cents per pound and zinc at 5 cents. Estimated with gold and silver at the same value as above, and lead at 50 cents per unit and zinc at 60 cents per unit, it has a value of \$19.50. When the products are sold, however, they will be sold about as follows:

In lead concentrate we will receive \$19 per ounce for gold, 47½ cents for silver, 3¼ cents per pound for 90 per cent of the lead (wet assay less 1½ per cent), 10 cents per unit for excess iron. We will pay \$3 freight and no treatment charge. This leaves us \$63.75 per ton net, or \$5.10 per original ton.

Iron concentrate will bring the same prices for gold, silver, lead and iron. We will pay same freight and about \$5.50 for treatment. This leaves \$11.31 per ton net, or \$1.57 per original ton.

The zinc concentrate, with spelter at 5 cents, and \$5.50 freight, will net \$19.30 per ton or \$5.02 per original ton.

These net receipts amount to \$11.69 per original ton, which is 31 per cent of the assayer's figure and about 60 per cent of the engineer's.

A careful analysis of all of the above figures will show that we have received net, \$11.38 per ounce for gold, 25.2 cents per ounce for silver, 2.09 cents per pound for lead, and 1.57 cent per pound for zinc, which figures may be

safely applied to this particular ore so long as the grade does not change materially. The contracts upon which I have figured settlements may vary to some extent, but the general result will be about the same.

From the above it will be apparent to the investor and to his engineer that the metal contents and market prices of the metals cannot be used as a basis of calculation of ore valuation until it is fully and definitely known where these metals will be recovered and what prices will be received for the various products.

Denver, Col.

A. M. PLUMB.

The Iron and Steel Market

The steel market turned quiet in the second half of December, but without losing a particle of its fundamental strength, the quietness being attributed to the usual holiday influence. Specifications on contracts expiring at the close of the month were as heavy as formerly, except for the influence that some buyers had already specified their limits. Most of the contracts, of course, were at relatively low prices.

On Dec. 15 the Carnegie Steel Company advanced its minimum price on bars, plates and shapes from 1.70c. to 1.80c., and as some of the other mills had already made such an advance the market became quotable at 1.80c. as minimum. Effective Dec. 21, the American Steel & Wire Company advanced wire prices \$2 a ton, other mills immediately concurring.

The steel mills enter the new year with a very large volume of specific business on books, actual orders which were taken with the understanding that they were not to be canceled or the price revised no matter what occurred in the market. There is also a large volume of contract business upon which heavy specifications can reasonably be expected. The steel producers feel confident that, barring actual accidents in the market, they will be called upon to operate at their fullest capacity throughout the year 1916. All are careful, however, to avoid making the semblance of a prediction as to what may occur when the war ends. Now that a much smaller proportion than formerly of the total steel output is passing into war material, the question of the possible cancellation of war orders is relatively insignificant. The great question is the general economic changes that may be wrought, affecting the various industries of the United States. There is also the question of foreign competition, not only in neutral markets but possibly even in the markets of the United States. There will be a feverish revival of commercial activity in the belligerent countries, but there is a wide range of opinion as to whether this will be on a basis of high costs or low costs. All eyes will be turned to the United States as the place where the money lies. If the production of steel abroad is resumed more rapidly than the consumption there is the possibility of the offering of such steel greatly disturbing the markets in the United States.

Production of pig iron and steel has not been materially increased since October, a rate of substantially full production having then been reached. A few additional units have become productive, and others have been speeded up somewhat, but the weather, of course, has been less favorable than in September and October, and it may be said that production has been at an unchanged rate, with no prospects of material change.

Pig Iron

The various pig-iron markets have continued their advances, though as formerly without the stimulus, apparently, of any really large buying. Unless the advances represent an unusual amount of courage on the part of the furnacemen, an unprecedented hopefulness for the future, one must conclude that the trade is

facing a definite scarcity of pig iron, as there has been for four months a scarcity of steel. Pig iron has now advanced, since the low level maintained so consistently during the late months of 1914 and the first six months of 1915, fully \$5 a ton. Such an advance is quite unusual. A moderate increase in demand serves to advance prices moderately, say, by from \$1 to \$4 a ton, merely through the operation of an economic law that as demand increases the less fit furnaces, with higher production costs, must be brought into operation. The market is now quotable as follows: No. 2 foundry iron, delivered Philadelphia, \$19.25 to \$19.75; at Buffalo furnaces, \$18; delivered Cleveland, \$18.80; at Chicago furnaces, \$18 to \$18.25; at furnaces, Birmingham district, \$14 to \$15; f.o.b. valley furnaces, 95c. higher delivered Pittsburgh: Bessemer, \$19.50 to \$20; basic, \$18 to \$18.50; foundry, \$18.50 to \$19; malleable, \$18 to \$18.50; forge, \$18 to \$18.50.

Steel

Since the scarcity of steel became acute there has been no regular open market for soft steel billets and sheet bars. The regular consumers were covered fairly well by long-term contracts, generally subject to a periodic adjustment of price, and the mills would not sell in the open market, or at least at such prices as would be paid by any considerable number of possible buyers. The pressure for billets has been accumulating, however, and some purchases of open-hearth are being made. One sale of about 2500 tons of soft open-hearth billets was made after the middle of December at \$35, maker's mill, Pittsburgh district, and that may perhaps be regarded as fixing a market. Bessemer billets are quotable at \$32 to \$33, with but little tonnage available at that range. There is no demand for sheet bars at such prices, since prices obtainable for sheets and tin plate would not justify, and the consumers simply depend upon such steel as they obtain on their regular contracts. Rods are about \$40 and forging billets about \$50 to \$55.

Finished Steel

Premiums for prompt shipment of plates are the rule, 2.25c. to 2.50c. being paid for small lots. Premiums are also occasionally paid for steel bars. Regular mill prices, f.o.b. Pittsburgh unless otherwise noted, are as follows:

Rails, standard sections, 1.25c. for Bessemer; 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.80c.

Shapes, 1.80c.

Steel bars and bands, 1.80c., base; steel hoops, 2c., base.

Iron bars, 2.009c. to 2.059c., Philadelphia; 1.75c., Chicago; 1.85c. to 1.90c., Pittsburgh.

Plain wire, 1.95c., base; galvanized wire, 2.65c.; wire nails, \$2.10 per keg, base; painted barb wire, 2.25c.; galvanized barb wire, 2.95c.

Sheets, blue annealed, 10-gage, 2.25c. to 2.75c.; black, 28-gage, 2.60c. to 2.70c.; galvanized, 28-gage, 4.75c. to 5c.; painted corrugated, 28-gage, 2.80c.; galvanized corrugated, 28-gage, 4.80c. to 5.05c.

Tin plate, \$3.60 for 100-lb. cokes.

Steel pipe, ¾ to 3-in., black, 78 per cent off list; galvanized 73½ per cent off list.

Boiler tubes (less than carloads), 68 per cent off list.

Structural rivets, 2.50c.; boiler rivets, 2.60c.

Cold-rolled shafting, 50 per cent off list.

Cold-rolled strip steel, 3.50c., base.

Non-Ferrous Metal Market

Dec. 27.—Unusual existing conditions are reflected in the metal market which is about as uncertain as the weather. Under normal conditions the last weeks

of the year would be dull. The present market made a good start in this direction early in December, but the dullness was not sustained and heavy sales have been made during the last two weeks, especially in copper, forcing this metal to a very high level.

Copper.—The price has been held at close to 20 cents all during December up to last week, when large sales forced the price to 21½ cents. On the 22nd, 60,000 tons was contracted for by England for 1916 delivery, at a price said to be 21 cents delivered. Producers control the market and the metal is liable to remain in a very strong position for some time to come. Exports for November were 23,168 tons of 2240 lb., while exports for December are running considerably ahead of November.

Tin.—The price of tin has moved within a comparatively narrow range in December, buyers refusing to become excited. Doubtless they are tired of being misled by the many wild rumors. An absence of inquiry characterized the market early in December. On the 16th England announced the curtailing of exports, which, while it excited the market some, only caused a 1¼-cent advance, and toward the latter part of the month a reaction took place. Prices varied between 37.25 and 40.00 for spot during the month.

Lead.—The Trust price was raised by 0.15 to 5.40 on Dec. 14. The market is in a strong position and the advances recently made were expected. December exports are running ahead of November, which were 5423 tons.

Spelter.—The decline of 3 cents per pound which took place in a few days around Dec. 1 lowered the price to about 15 cents. Sellers became excited and attempted to unload their stocks. By the middle of the month sellers were refusing to quote, which shows how erratic the market is, or how erratic it is being made. For several days sellers refused to quote, consequently the market became excited and the price advanced to about 17.50 cents spot with slight variations up and down. At the time of writing spot spelter was 17.35-17.50.

Other Metals.—Aluminium held up well until Dec. 20, when the extreme dullness caused a decline, which forced the metal to 53.00-55.00. On the 27th it was quoted at 54.00-56.00. Antimony remained practically unchanged during December at 39.00-39.50 for both American, Chinese and Japanese. Silver was up to 56¼ on Dec. 6, since when it has gradually dropped to 53¾. Tungsten continues at about \$60 a unit for concentrates, platinum prices are nominal at \$88 to \$100 per ounce. Quicksilver is quoted at \$125-\$130 per flask.

One Hundred and Twelfth Meeting of American Institute of Mining Engineers

The 112th meeting of the American Institute of Mining Engineers will be held in New York City, Monday, Feb. 14, to Thursday, Feb. 17, inclusive. The committee on arrangements consists of David H. Browne, chairman; Bradley Stoughton, vice-chairman; Lawrence Addicks, P. E. Barbour, G. D. Barron, J. V. N. Dorr, J. R. Finlay, L. D. Huntoon, Burr A. Robinson, E. M. Shipp, Joseph Struthers, E. B. Sturgis and R. H. Vail.

A smoker and entertainment will be held on Tuesday evening, Feb. 15, which the committee in charge promises will be well worth attending. The annual dinner will be held at the Hotel Astor on Wednesday evening, Feb. 16, and the presence of ladies is urged. The dinner will be followed by dancing.

The entertainment of the ladies will be in charge of

the Ladies' Committee, of which Mrs. Louis D. Huntoon is chairman. A very complete program of entertainment has been provided for the ladies, including luncheons, teas, dances, theatres and a visit to the art galleries of Senator Wm. A. Clark. The ladies are also especially urged to enjoy the all-day boat trip which has been arranged for Thursday. By courtesy of the Secretary of the Navy a naval vessel will be provided for a cruise around the harbor. The firing of some of the large guns will be witnessed.

Monday evening, Feb. 14, will be "college night." A Committee on Reunions, of which Dr. Joseph Struthers is chairman, will be in charge. It is expected that many formal gatherings of college alumni will be held.

Many clubs kindly offered the extension of privileges to members last year, and it is expected they will do the same this year. All the facilities of the United Engineering Building will be at the service of the members and their guests, and from the looks of the preparations which are being made a very interesting and comfortable time should be had by all those attending.

The technical program will contain many interesting papers in the various sections on the different metals, petroleum and gas, mining and milling methods, coal, coke, geology, etc.

Meeting of the Naval Consulting Board

The U. S. Naval Consulting Board was in session on Dec. 22 and 23. The first day was mainly devoted to meetings of the different sub-committees, where general pending subjects were discussed and further steps were proposed for future work. On the evening of Dec. 22 the members were the guests at a short informal monthly dinner of the American Institute of Mining Engineers and then promptly left for the general meeting of the board.

The next day was devoted to an inspection of the submarines and battleships now assembled at the Brooklyn Navy Yard, after which another general meeting was held. At the meeting, the laboratory committee, consisting of Edison, chairman, and Baekeland, Whitney and Woodward as members, presented its final report and recommendations, which were accepted with much enthusiasm by the other members of the board as well as by the admirals who were present at the discussion. The laboratory provides for adequate facilities to make all tests and experiments relative to the construction and operation of men-of-war or ordinance and ammunition without the present delays which hamper so much the construction work of anything new and which compel postponement of trials of things until it is too late to make a change. In this respect alone the proposed laboratory would introduce an enormous saving of expenses aside from preventing the present unavoidable delays in the construction of our means of defense. Some time ago a firm which was more than one year behind in its deliveries, simply answered that the construction work involved a set of new devices, each of which involved serious problems which delayed the work, because the necessary data had to be gathered during construction work, which increased enormously the cost as well as the period of construction.

Among other reports which were communicated, we should mention the recommendation by the sub-committee on ordinance and explosives, that the Government of the United States should erect at least one unit for the synthetic manufacture of nitrates or nitric acid, so as to get at least one plant, however small, in which to learn to produce the indispensable chemical for the manufacture of smokeless powder or modern explosives. This unit would permit to train a staff of competent

engineers or chemists to acquire the necessary experience and to provide means so that in time of war immediately other units could be added in a relatively short time. The plans, drawings, and specifications would be prepared in advance for such an emergency, and the initial staff would be able to train additional men for the work.

As matters stand now, it would be of little use to be equipped with best guns and warships as long as an enemy could easily seize the nitrate fields of Chile or occupy the ports of shipment of the valuable material. At present this country can provide within itself practically all other indispensable materials for war, except nitrates. Private industry has not gone into the matter of synthetic nitric acid here in the United States, because it can find better employment for capital in other chemical industries as long as it is so cheap and easy to import natural Chile saltpeter.

The Government might be able to run the enterprise at a small profit, or even at some loss, and use the produced nitrate for its own smokeless powder and explosive plants, or sell it as fertilizer and charge the relatively small investment as part of its equipment for defense while at the same time keeping abreast with an industry which ultimately may have an immense importance as a supply of cheap fertilizer for agricultural purposes.

The United States can well afford in its policy of conservation to set apart for this purpose one of the large water powers under its control.

The committee on manufacturing and standardizing is busying itself with extending the rational methods of manufacturing now adopted by the automobile manufacturers of this country to the rapid manufacture of aeroplane motors, and also proposes means whereby men of the army or the navy who want to become proficient in aeronautics will have the benefit of the unusually well provided instruction classes of the associated automobile manufacturers of this country free of charge to the Government.

In further accord with the idea of mobilizing the industries of the country a definite plan is being developed whereby the whole United States is divided into sections, and in each section a census is to be taken of the different industrial establishments and their equipment, and, furthermore, all necessary information is to be furnished to the manufacturers so as to enable them to convert their plants at shortest notice in time of war to contribute with best efficiency to the manufacture of ammunition and general supplies.

We are told that some other matters were presented and discussed, which, however, are not considered advisable for publication.

All these entirely practical tendencies of the Naval Board contradict flatly any apprehension which the ill-informed might have as to the vagaries of what they supposed to be a board of "long-haired inventors"—long-headed would be a more suitable definition.

Program of Meeting for Presentation of Perkin Medal to Dr. Baekeland

The presentation of the Perkin Medal to Dr. L. H. Baekeland will take place on Jan. 21, at a meeting of the Society of Chemical Industry in joint session with the American Chemical Society and American Electrochemical Society. The meeting will be held in Rumford Hall, Chemists' Club, at 8 p. m. The program includes the presentation speech, which will be made by Dr. C. F. Chandler, and the speech of acceptance by Dr. Baekeland.

The Western Metallurgical Field

The Everson Flotation Patents

Renewed public interest in the contributions of Carrie J. Everson to the process of concentration by flotation has been aroused by investigations started by the Colorado Scientific Society with a view to ascertaining her whereabouts and the incidents that led to her inventions. The Everson patents, issued to Carrie J. Everson of Chicago, Ill., (348,157, Aug. 24, 1886) and to Charles B. Hebron and Carrie J. Everson of Denver, Col., (471,174, March 22, 1892) disclose not merely the essentials of flotation as practised to-day, but enter into refinements of the process that show an unusually complete investigation.

In one section of the specifications, for example, it is stated that: "The essential feature of the method which constitutes my invention, therefore, consists in commingling with pulverized ore a fat or an oil, either animal, mineral or vegetable, or a fatty constituent or acid of an animal or vegetable fat or oil, or any constituent of a mineral oil, together with an acid, either mineral or vegetable, or a soluble neutral or acid salt, for the purpose of effecting a union of the free metal or metallic portion of the ore with such admixed material, whereby the same may be retained in the subsequent separation of the quartz or other rock, therefrom by washing or other suitable means."

Among the ores on which the inventor had successfully operated, are listed those containing native gold and silver, cerargyrite, argentite, argentiferous galena and a variety of double sulphides of silver, with copper, arsenic, antimony and other base metals. Pyrite containing gold and silver, and tellurides of gold and silver also were treated. Among the oils used are specified petroleum, paraffin oil, tallow, lard, lard oil, red oil (impure oleic acid), cotton-seed oil, castor oil, sperm and linseed oils. The list of acids includes sulphuric, hydrochloric, nitric, phosphoric, acetic, oxalic, tannic and gallic. The following salts also were used: sulphates and chlorides of sodium, zinc and copper and the double sulphate of potash and alumina.

Here is an unusually broad disclosure of factors which subsequent experience has proved essential to success, either when used singly or in combination. The ores mentioned are such as are treated to-day; the oils are similar, and, of course, the acids are practically the same as now used when deemed necessary. The mention of certain salts, such as sodium, zinc and copper sulphates and chlorides, is significant of the extent to which the research was carried, for it has been observed by later investigators that salts in solution are almost essential to good work. Practically pure water has been found a poor medium in which to work, and the addition of copper sulphate has, in a number of cases, proved the saving factor.

The investigation of the Colorado Scientific Society into the early history of the Everson patents was undertaken with a view to commemorating what now appears to have been a remarkable piece of research on the part of a Colorado woman; to establish the historical facts with accuracy and to prove or disprove, if possible, the legendary reports of the inception of the process. Up to date the following facts have been established with certainty: that Mrs. Carrie J. Everson was the wife of a physician, and for many years a resident of Denver, where she engaged in charitable work as a nurse. She was not a Denver school teacher and had no brother who was a Denver assayer.

The last few years of her life were spent in California, where she died at the age of 73, Nov. 3, 1914, at San Anselmo.

New Smelter Construction

Since 1907 the Coeur d'Alene district of Idaho has been second to Missouri in lead production in the United States; but in spite of the large quantity of ore and concentrate produced, none of the output has been smelted locally. The product has been shipped to smelters in Colorado, Utah and other States for reduction. It now appears that the Bunker Hill & Sullivan Mining & Concentrating Company is to erect a smelter in the Coeur d'Alene district, possibly near Kellogg, for the treatment of its own output and that of other mines in the district. The definite location of the plant has not yet been settled, but plans are in the hands of Jules LaBarthe, of Bradley, Bruff & LaBarthe, of San Francisco, and it is expected that definite announcement of location will soon be made. The establishment of this smelter is expected to prove of great value to the lead-mining industry of Idaho, and the outcome of the venture will be watched with interest.

Other Coeur d'Alene companies have interested themselves in the purchase and rehabilitation of the smelter at Northport, Wash., and this plant is expected to be in operation early in 1916. The Tamarack & Custer and Hercules companies are represented in the new Northport Smelting & Refining Company, of which J. J. Day is president, E. R. Day secretary-treasurer, and Edward Boyce, E. R. Knight and F. M. Rothrock directors. The plant is to be equipped for both lead and copper smelting. Lead ores will be received from the mining companies directly interested in the smelter, and custom ores from other companies in the Coeur d'Alenes. A supply of copper ore is now being arranged for in the Chewelah district.

Fields Flotation Process at Ohio Copper Mill

It is announced that the Fields flotation process is to be tried experimentally at the mill of the Ohio Copper Company, near Salt Lake City, Utah. Some months ago arrangements were made for a test of this process at the Ohio mill, but the company became involved in financial difficulties which deferred action in the matter. The process is one developed by John D. Fields at the Royal Basin property, Maxville, Mont., and is conducted in an electrolytic cell. Electrolysis is said to produce two results: the generation of gas to buoy the oiled sulphide minerals, and the deposition of copper dissolved by the action of acid on oxidized minerals which may be present in the ore. The work of installing the 25-ton experimental unit is in charge of Lee M. Walton, representing the Fields company.

Activity in the Joplin District

In no section of the country have the high prices for zinc and lead had a more marked effect than in the Joplin district of Missouri. Early in November the valuation of zinc and lead produced in 1915 was in excess of \$20,000,000, or more than \$2,000,000 greater than for 1912, the previous banner year. With the output for November and December to be added to the production to date, the total valuation for 1915 will approximate \$24,000,000. The production of blende is forecasted at 250,000 tons, calamine 18,000 and galena 42,000. For the week ended Nov. 14, the base price paid for blende concentrate containing 60 per cent zinc ranged from \$85 to \$110. For the corresponding week of 1914 the range was \$40 to \$44. Calamine has been in strong demand at \$65 to \$75, basis of 40 per cent zinc, as compared with \$19 to \$21 a year ago. Galena ranged from \$60 to \$64, basis of 80 per cent lead, compared with \$42 at a corresponding period in 1914.

These conditions have stimulated mill construction which has proceeded at an unprecedented rate, both for

the treatment of old tailings and ore from new development. In the Cartersville district a 300-ton mill has been built on the Old Century and Herald mines; a 150-ton tailing mill on the land of the South Cartersville Mining Company; a 300-ton mill by the Ben Franklin company; a 250-ton mill for the Queen Esther company. The mill of the Twin Cities company has been remodeled.

At Galena a 750-ton tailing mill has been built on the Squires land; and the Grand Tower Mining Company has given a contract for the construction of a 150-ton mill on the Campbell land.

The Kusa smelter is a new plant in Oklahoma which will treat Joplin ore.

Arizona Copper Company's Fire Loss

The troubles of the Arizona Copper Company, due to labor difficulties since September, were augmented on the fifth of November by the destruction by fire of parts of the concentrating plant at Clifton. The loss is estimated variously at from a quarter to a half million dollars. As soon as the fire was discovered in No. 2 concentrator it was fought by the local fire department and men on strike. Before it was controlled the flames had destroyed No. 3 department also, and was checked only by the use of dynamite. Union sympathizers state that the fire was due to defective wiring, but this is not accepted by the company officials. It is reported that new plants will be erected as soon as labor troubles are settled.

Company Reports

In the annual report of the Nevada Wonder Mining Company is contained the résumé of operations by the Churchill Milling Company, which treats Nevada Wonder ore. The mill made a record during the year ended Sept. 30, 1915, treating 58,124 tons of ore, an average of 159.2 tons per day, and an increase of 26.1 tons per day over the preceding year. Based on actual running time, the stamps showed a tonnage of 18.01 per stamp per twenty-four hours. Gold recovery was 95.3 per cent and silver 93.68 per cent. Direct milling cost was \$2.268 per ton; indirect, \$0.545; total cost, \$2.813 per ton. Cost of power per ton was \$0.394; supplies, \$1.166; labor, \$0.705.

The Granby Cons. Mining, Smelting & Power Company, Ltd., smelted 1,098,020 dry tons of ore at its Grand Forks and Anyox plants in British Columbia during the year ended June 30, 1915. Of this amount only 24,583 tons was foreign ore. The production was 26,638,912 lb. refined copper, 377,881 oz. fine silver and 31,388 oz. fine gold. The cost of Granby copper was 10.66 cents per pound. Conditions at the new Anyox plant have improved as operations have proceeded. New charge cars have modified the feeding and distribution of the ore in the furnaces so that less trouble is experienced from crusts in the shafts. A new furnace, No. 4, and an agglomerating plant have been added to the equipment. Due to the erratic silica content of the ores received it has been impossible to operate on the semi-pyritic basis as contemplated, with low coke and little flux; but with the development of the company's own ore bodies it is expected that conditions can be more closely controlled. It is expected that the making of converter grade of matte in the first smelting will finally be accomplished. At Grand Forks the plant was closed from Aug. 7 to Dec. 7, 1914, and has since been put in full operation. Operations at this plant are on a well established basis and few difficulties are encountered. The cost of smelting was \$1.187 per ton, as against \$1.214 for 1913.

The average percentage of coke used per ton of ore was 13.17.

Baltimore Meeting of American Institute of Chemical Engineers

The eighth annual meeting of the American Institute of Chemical Engineers will be held in Baltimore, Md., from Wednesday to Saturday, Jan. 12 to 15, 1916.

On Wednesday, Jan. 12, the annual business meeting will be held at 10 a. m., at the Emerson Hotel, followed at 11 a. m. by the reading and discussion of the following two papers:

The Development of the Manufacture in the United States of Products Derived from Coal, by H. W. Jordan.

The Cracking of Petroleum and Other Hydrocarbons as a Chemical Engineering Problem, by W. F. Rittman.

In the evening of Wednesday, at 8 p. m., a meeting will be held at Johns Hopkins University, when the following three papers will be presented:

Ethyl Alcohol from Wood Waste, by A. D. Little.

The Production of Ammonia from Cyanamid, by W. S. Landis.

The Barium Industry, by M. Toch.

On Friday, Jan. 14, after a business meeting, at 9 a. m., a professional meeting will be held at 10 a. m., at the Emerson Hotel for the reading and discussion of the following papers:

A New Process of Bleaching, by S. F. Peckham.

Lutes and Cements for Chemical Purposes, by S. S. Sadtler.

On the evening of Friday, a joint meeting will be held with the Baltimore Section of the American Chemical Society at Johns Hopkins University, when Mr. Powell, of the Baltimore County Water Co., will discuss ozone purification of water and Dr. H. E. Ives will read a paper on artificial daylight.

On the evening of Thursday, a subscription dinner will be held at 8 p. m., at the Emerson Hotel. On the evening of Friday, a smoker will be tendered at the Johns Hopkins Club by the Maryland Section of the American Chemical Society.

The following excursions have been arranged:

For Wednesday afternoon, to the sewage disposal plant of the City of Baltimore and the ozone water purification plant of the Baltimore County Water Co., or to the plant of the Maryland Steel Co. at Sparrow's Point.

For Thursday (all day), to Emerson Drug Co. (bromo seltzer manufacturers) and to the Naval Academy in Annapolis.

For Friday afternoon, to the Maryland Glass Company and Crown Cork and Seal Company or to the Standard Fertilizer Works.

For Saturday, to McCall's Ferry Power Plant of the Pennsylvania Water & Power Co. or to the Tidewater Portland Cement Co., at Union Bridge, Md.

Members will be welcome at the chemical and physical laboratories of Johns Hopkins University any day during the meeting between 9 a. m. and 5 p. m.

The local committee consists of Messrs. Richard K. Meade, J. G. Dailey and W. T. Van Horn, while Dr. E. Emmet Reid represents the Maryland Section of the American Chemical Society on the committees.

Prof. J. C. Olsen, Cooper Union, New York City, is secretary of the American Institute of Chemical Engineers.

Coal in the United States.—The recently issued annual report of the Geological Survey for 1914 on the production of coal contains an interesting chart of the yearly production of coal from 1807, the date of the first discovery, to 1914.

Thermal Reactions in the Vapor Phase of Various Coal Tar Oils and Distillates*

BY WALTER F. RITTMAN AND GUSTAV EGLOFF

Previous experiments of the present general series have indicated clearly the direction and mechanism of thermal reaction among hydrocarbons. It has been shown¹ that paraffin hydrocarbons tend to form: (1) other paraffin hydrocarbons of smaller molecular weight, (2) unsaturated aliphatic hydrocarbons, and (3) aromatic hydrocarbons of mono- and poly-cyclic series. It has been shown also that inter-aromatic reactions may be arranged in a definite and consistent series. Mono-cyclic compounds with aliphatic side chains tend to form benzene, and benzene is decomposed by heat into naphthalene, anthracene and other poly-cyclic compounds.

A study² of the relative content of aromatic hydrocarbons of cracked petroleum mixtures led to conclusions of the same sort. It appeared that toluene and xylene were the products of less strenuous conditions of cracking than benzene, and it appeared also that naphthalene and anthracene were the results of the decomposition of the mono-cyclic compounds. In all the work it was indicated in a definite manner that the reactions are practically irreversible. For instance, no appreciable quantity of benzene is formed by the heating of naphthalene.

SCOPE OF THE PRESENT WORK

The present experiments were conducted for the purpose of testing the utility of various low-grade coal tar oils and distillates as original material for the production of the valuable hydrocarbons, toluene and benzene. On the basis of indications furnished by the results of previous work, it appears that transformations may be effected advantageously with such mixtures as contain mono-cyclic compounds with aliphatic side chains. The higher boiling distillates of the light oil cut, containing such hydrocarbons as xylenes, ethyl benzene, mesitylene, and cymene, would appear the most promising material possible, since the change involves only the simple splitting of a side chain attached to an exceedingly stable cyclic nucleus. On the other hand, products which consist chiefly of compounds with poly-cyclic nuclei would not seem to be utilizable, since the results of all previous experiments have indicated that the simpler hydrocarbons cannot be produced by the breaking down of the more complex aromatic compounds.

EXPERIMENTAL

The method of procedure was, in general, the same as that which has been adopted for all the series of experiments on vapor phase reactions of hydrocarbons. Details of operation were identical with those of the experiments³ in which pure aromatics were used as original materials. The oils were run through an electrically heated cracking furnace, and the resulting products collected and studied. The yields of solid, liquid and gaseous products were measured and the liquids analyzed. The latter were distilled with Hempel fractionating columns and cuts made at 75 deg., 100 deg., 125 deg., 150 deg., and thereafter at intervals of 50 deg. Specific gravities of the recovered oils and of the distillation cuts were measured. The fractions coming over at higher temperatures were examined for the presence of naphthalene and anthracene by the

simple method of chilling and noting the appearance of solid matter frozen out.

OILS USED AS ORIGINAL MATERIAL

The oils used as original material were all coal-derived products and were either of medium or of low cost. Their properties are indicated by the following descriptions:

Solvent Naphtha was a hydrocarbon mixture of slightly higher boiling point than the benzene and toluene fractions of coal tar and probably consisted chiefly of xylenes and cymene. It usually sells for a low price and is used as a solvent; but is now in such demand that it is moderately expensive, although still much cheaper than benzene and toluene. The sample used in the present experiments was obtained from a large company specializing in the working up of coal-tar products.

Creosote Oil was the ordinary product sold under that name. The sample employed in the present experiments was obtained from a second company handling coal-tar products.

Light Dead Oil was one of the typical low grade coal-tar fractions. It was obtained from the second company mentioned.

Naphthalene Wash Oil was the drip oil which comes from the presses used in separating naphthalene. It was obtained from the company furnishing the two preceding oils.

Imperial Varnish Oil was similar in properties to the solvent naphtha but was slightly heavier than the product usually sold under the latter name. The sample was obtained from a company operating in Canada.

Heavy Dead Oil was slightly heavier than the light dead oil, but contained a larger percentage of constituents boiling below 200 deg. C. It was obtained from the company furnishing the solvent naphtha.

Light Tar Oil was an intermediate product between the solvent naphtha and the creosote oil. It was similar in properties to the light dead oil.

Secondary Oil Residue was a product obtained from a steel company which operates its own by-product coke ovens. The oil was the residue left after a distillation of the product obtained by the primary fractionation of the saturated wash oil coming from the gas scrubbers.

GENERAL RESULTS OF EXPERIMENTS

Results of the present series of experiments appear in Table I. It will be noted that the sets of experiments performed for the various oils were irregular. This is accounted for by the fact that it was not considered necessary to study systematically the effects of temperature and pressure. In several cases the number of experiments performed with a single oil was limited by the size of the sample. In most cases conditions of temperature and pressure were selected which had been indicated by previous general experience as most favorable for cracking the oils in question. A few runs sufficed to yield positive results with some products, while with others, when results were of a negative nature, the ranges of temperature and pressure were more extensive. In all cases the results obtained were entirely in accord with what was expected from theoretical considerations and from the indications of previous experience.

The figures in Table I represent the specific gravities, percentage recoveries, and quantities of carbon formed, as well as the composition of the recovered oils. Distillation cut figures are given in terms of the original oil rather than on the basis of recovered oil. This in all cases reduces the apparent magnitude of the yields of benzene and toluene.

SECTION B. PERCENTAGE RECOVERIES WHEN PETROLEUM IS CRACKED BY THE VAPOR PHASE METHOD

Temp., deg. C.	600	600	600	600
Pressure, atmosphere	1	1	1	1
Pennsylvania	59.9	31.4	43.6	40.5
California	46.6	43.9	52.5	33.7

Distillation cuts are in terms of original oil, the values given being obtained by multiplying the actual distillation figure obtained by the percentage recovery.

The volume of original oil used in each run was 560 cc.

Pressures are given in approximate atmospheres. The actual pressures were atmospheric and 100 pounds, 150 pounds, 175 pounds, and 200 pounds above atmospheric. The latter four pressures are approximately 8, 11, 13, and 15 atmospheres.

MAGNITUDE OF PERCENTAGE RECOVERY

In Table II are given the figures for percentage recoveries, these being collected from Table I. The first point to be noted is that these values are considerably greater than those for recoveries from petroleum cracked under approximately similar conditions. A few figures are given, taken from the results of a previous set of experiments.¹ California and Pennsylvania oils were selected as representative of different classes. The observation that coal-tar oils are less extensively

decomposed than petroleum is exactly what would be expected, since the former are the products of a primary thermal decomposition at high temperature.

It may be observed also that there are more or less characteristic variations among the different coal-tar oils, which, however, on account of the irregularity of the series it is not possible to indicate by averages. The general tendency is toward greater decomposition on the part of those oils which have larger percentages of mono-cyclic constituents (indicated by the magnitude and specific gravity of the cut distilling below 200 deg. C.).

¹Rittman, Jour. of Ind. and Eng. Chem., 7 (1915), 945.

SPECIFIC GRAVITY OF RECOVERED OILS AND PERCENTAGES OF CARBON FORMATION

No points of particular interest are brought out by the figures for specific gravities of recovered oils and percentages of carbon formation. These values have not, therefore, been retabulated. The one observation which may be made is that neither the changes in specific gravity, due to cracking, nor the percentages of carbon formed, are as great as in cases when petroleum was the original material. This is again in accord with what would be expected when consideration is given to the fact that the coal-tar oils are the products of a primary thermal decomposition at high temperature.

FORMATION OF BENZENE AND TOLUENE

The essential point concerning which information has been sought in the present experiments is the degree of formation of the commercially valuable hydrocarbons, benzene and toluene. Since the products are not contaminated with any considerable quantities of aliphatic hydrocarbons their degrees of formation may be represented by the magnitude of the respective distillation cuts, 75–100 deg. and 100–125 deg. In the present case the amount of original oil distilling up to 200 deg may, likewise, be taken as representative of its content of mono-cyclic aromatics. The figure 200 deg. is not strictly accurate and a temperature of 15 deg. to 20 deg. lower would be better; but, as no cuts were made at this point, it cannot be used as a limit of separation. It has seemed that there ought to be an approximate relation between the amounts of benzene and toluene formed and the percentage of mono-cyclic aromatics in the original oil. That such a relation exists is indicated by the figures collected in Table III.

The following values appear:

Column I.—Percentage of benzene cut, on basis of original oil.

Column II.—Percentage of toluene cut, on basis of original oil.

Column III.—Sum of percentages of benzene and toluene cuts.

Column IV.—Percentage of original oil distilling below 200 deg. C.

Column V.—Ratio representing the degree of transformation of the 200 deg. C. original cut into benzene and toluene. This figure is obtained by dividing the value in Column III by that in Column IV.

Column VI.—Conditions of temperature and pressure under which the oils were cracked in the runs for which figures are given.

The figures are in all cases for optimum runs; those being selected which gave maximum total yields of benzene and toluene. With one exception the figures in Column V are of the same order. They indicate that the quantity of benzene and toluene formed cannot exceed the content of the original oil of mono-cyclic hydrocarbons and that the degree of formation seems to have

a maximum limit of about 50 per cent. The figures obtained would undoubtedly agree even more closely than they do if it were not for the necessary inaccuracies of assumption and of experimental manipulation. The case of the creosote oil is difficult to explain on the basis of any of the more probable causes of inaccuracy, but as it deals with a small 200-deg. cut and a small quantity of benzene and toluene formed it does not seem of great importance.

In general, it appears that by cracking under optimum conditions somewhere between 20 and 40 per cent of the portion of the original oil distilling below 200 deg. C. may be converted into benzene and toluene. The figure probably may be in extreme cases as low as 10 per cent or as high as 50 per cent.

While the indications of Table III are only qualitative and approximate, they are still of great value in determining the utility of coal tar distillates for transformation into benzene and toluene. Products like the creosote oil and the light dead oil are unquestionably useless as raw material for this purpose. Products like the solvent naphtha and varnish oil are the best possible material, although their use may be restricted on account of the factor of cost.

SUMMARY

Several coal-tar oils and distillates, all of the class less valuable commercially, have been subjected to cracking by the vapor phase method. Conditions of temperature and pressure have been chosen which seemed particularly adapted to the oils in question.

It appeared that percentage recoveries were high, as compared with those obtained when runs were made with petroleum as original material. Changes in specific gravity of liquid product and degrees of carbon formation are likewise lower than in the case of petroleum. These results were expected in consideration of the fact that the coal-tar products have once before been subjected to high temperature and brought at least approximately to equilibrium.

Oils and distillates having a considerable percentage of constituents distilling below 200 deg. C. yield large quantities of benzene and toluene, the yield being generally between 20 and 40 per cent of the 200 deg. cut from the original oil. Oils having minor percentages of constituents distilling below 200 deg. yield the same proportion of the desired hydrocarbons, but as this is likewise a small quantity they are undesirable material for transformation.

The failure to obtain benzene and toluene in such quantities as to indicate that hydrocarbons boiling above 200 deg. have been transformed is in accord with previously obtained results.*

These demonstrated that inter-aromatic reactions are irreversible, and that they proceed in the order indicated by the following series:

*Rittman, Byron, and Egloff, loc. cit. Rittman and Twomey, loc. cit.

TABLE III.—BENZENE AND TOLUENE FORMATION, AS INFLUENCED BY CONTENT OF MONO-CYCLIC AROMATICS OF ORIGINAL OIL. RATIO BETWEEN AMOUNT DISTILLING UP TO 200 DEG. IN ORIGINAL OIL AND THE SUM OF THE BENZENE AND TOLUENE CUTS

Column No. I	II		III	IV	V	VI	
	Benzene	Toluene	Benzene and Toluene	200 Deg. Orig. Distillate	Ratio Between III and IV	CONDITIONS OF CRACKING	
						Temp., Deg. C.	Pressure, Atm.
Solvent naphtha	9.9	19.5	29.4	79.9	.37	600	8
Creosote oil, . . .	2.6	1.9	4.5	2.5	1.8	600	11
Light dead oil, . . .	2.7	1.7	4.4	9.5	.46	700	15
Naphthalene wash oil	4.1	3.3	7.4	25.7	.29	600	8
Imperial varnish oil	6.8	10.7	17.5	64.5	.27	650	8

Experiments on the Separation of Vanadium from Crude Sodium Uranate*

BY HOWARD H. BARKER AND HERMAN SCHLUNDT

In the extraction of radium from carnotite ore considerable quantities of uranium and vanadium compounds are obtained as by-products. When the uranium is separated by precipitation as sodium diuranate, $\text{Na}_2\text{U}_2\text{O}_7$, from solutions also containing compounds of vanadium a crude uranate of sodium is obtained, generally bearing from 5 to 10 per cent vanadium, expressed as the pentoxide, V_2O_5 . Our experiments constitute a study of several laboratory methods for the separation of vanadium in the crude uranate, and the conversion of the uranate into uranium oxide.

Since sodium vanadate is very soluble in water and sodium uranate is not, we would expect that the vanadium could be completely separated from the vanadium bearing uranate by solution of the latter in one of the mineral acids, and precipitation of the uranium by the addition of sodium hydroxide in excess. This operation does remove about one-half of the vanadium, but the yellow uranate of sodium still contains too high a percentage of vanadium for market demands. To reduce the percentage of vanadium pentoxide to less than one-half of 1 per cent by this method would evidently require four to five repetitions. Our experiments were directed toward finding a more direct method of removing the vanadium.

The stock supply of crude uranate used in these experiments was furnished by the National Radium Institute through the courtesy of Mr. R. B. Moore, physical chemist of the U. S. Bureau of Mines, in charge of the radium investigations at Denver. Several pounds of this material were ground and sampled. An analysis was made by following, in the main, the directions given in Bulletin No. 70, U. S. Bureau of Mines, page 88, for the analysis of carnotite ores. The results of the analysis are summarized in Table I.

TABLE I.—ANALYSIS OF CRUDE URANATE—PERCENTAGES

Constituent	Sample No. 1	Sample No. 2	Average
Water at 120 deg	2.91	3.33	3.12
Water of constitution	7.03	6.40	6.72
Insoluble residue	0.28	0.31	0.29
Copper and tin group oxides	0.23	0.37	0.30
Calcium oxide, barium oxide and ferric oxide	5.96	6.01	6.00
Uranium oxide (U_2O_7)	64.26	65.90	64.63
Vanadium oxide (V_2O_5)	8.60	8.50	8.55
Sodium (metal)	7.90	8.33	8.12
Total			97.73

The apparently low total is due to the fact that for every three molecules of sodium diuranate, $\text{Na}_2\text{U}_2\text{O}_7$, there are five atoms of oxygen which are not accounted for in the above results. If we calculate the amount of oxygen to be added, assuming that the crude uranate contains 64.63 per cent of the oxide, U_2O_7 , the per cent of oxygen not accounted for would amount to 3.07 and the total percentage then is 100.8.

Working on a laboratory scale, we have succeeded

in reducing the vanadium content of the crude uranate to less than one-half of 1 per cent by several methods: (1) Removal of the vanadium as a volatile product by treatment with hydrochloric acid gas. (2) Treatment with ammonium chloride. (3) Separation of vanadium by treatment with some of the common mineral acids.

Treatment of the Crude Uranate with Hydrogen Chloride

Edgar F. Smith and Joseph B. Hibbs¹ first showed that vanadic acid can be completely removed from sodium vanadate as a volatile product by means of hydrochloric acid gas. Later, it was shown by Hillebrand that a part of the vanadium in ores, the vanadous compounds, are not completely removed by this method. Our first experiments were undertaken to ascertain whether the vanadium in the crude uranate can be volatilized by hydrogen chloride. The crude uranate was subjected to the action of hydrochloric acid under varying conditions of temperature. It was found that crude sodium uranate which had been ignited in the free flame to remove moisture present, and then subjected to dry hydrogen chloride evolves brown fumes characteristic of the chlorides and oxychlorides of vanadium. The reaction proceeds fully as well at room temperatures as when the uranate is heated. Evidently the reaction produces enough heat to raise the temperature sufficiently to volatilize the chlorides and oxychlorides of vanadium.

During the process a slight caking is produced as a result of the water formed in the reaction, and this sometimes prevents the hydrogen chloride from interacting with the vanadium in the interior of the uranate. In such cases it is necessary to heat the uranate residue to a temperature high enough to expel all the moisture present, then to grind it to a fine consistency. When hydrogen chloride is passed over it a second time a slight evolution of brown fumes is again observed, showing that only traces of the vanadium are left. Two treatments with hydrogen chloride gave a very complete quantitative separation of the vanadium.

The residue left after the separation of vanadium probably is a mixture of sodium chloride, sodium uranate, and uranyl chloride. This residue is readily soluble in dilute acids, from which the uranium can be obtained in the form of oxides by either precipitation with ammonia and ignition of the uranate, or else by boiling with ammonium chloride, which likewise converts the major part of the sodium uranate into ammonium uranate.

In subjecting the vanadium bearing uranate to the action of hydrogen chloride, the uranate was placed in a long, hard-glass tube of 1-cm. bore. One end of the tube was fitted with a one-hole stopper, carrying a glass tube. A steady stream of hydrogen chloride was passed over the uranate in the tube and maintained until the evolution of the brown fumes ceased. The reaction was carried out at different temperatures by placing the glass tubes in a combustion furnace and regulating the temperature.

In order to get some idea of the quantitative separation of the vanadium from the crude uranate by this method, the volatile compounds of vanadium from a weighed sample of uranate were absorbed in water. The aqueous solution of vanadium was oxidized with hydrogen peroxide, and evaporated nearly to dryness with sulphuric acid. It was taken up with water and reduced with sulphur dioxide. The solution was then boiled to expel the excess of sulphur dioxide, after which the hot solution was titrated with a standard solution of potassium permanganate. The amount of

*Extract of a thesis submitted by Howard H. Barker in the Graduate School of the University of Missouri in partial fulfillment for the degree of Master of Arts, June, 1915.

¹Jour. Am. Chem. Soc. 16, 578 (1894).

vanadium in the aqueous solution was found to vary from 8 to 8.2 per cent of V_2O_5 , as against 8.55, the amount actually found in the crude uranate by analysis. This result shows that the vanadium is nearly removed quantitatively. The residue showed only a feeble test for vanadium.

Whether this method can be conducted on a commercial scale is an open question. In designing a large form of apparatus, a chemical engineer must consider the following points: (1) The material to be used in the construction of the apparatus, wood, metal or stone-ware. (2) The process should be made continuous. That is, all the hydrogen chloride should be utilized by passing that which is rich in the products of the reaction over fresh crude uranate. (3) The water formed during the reaction is sometimes very objectionable, as it produces caking. The apparatus should, therefore, have a stirring device. (4) Some provision should be made for collecting the volatile vanadium compounds. (5) An efficient hydrogen chloride generator is an important part of the apparatus.

After removal of the vanadium by this method, the next step is the conversion of the uranium compounds into urano-uranic oxide (U_3O_8). One of the commercial methods of conversion consists in boiling the sodium uranate with a concentrated solution of ammonium chloride. Ammonium uranate is produced, but the conversion is not complete. Upon ignition, the ammonium uranate is decomposed, yielding uranium oxide. A mixture of uranium oxide and sodium uranate is thus obtained, from which the sodium uranate is removed by digesting with dilute sulphuric or hydrochloric acids. From 10 to 15 per cent of the uranium oxide, however, is also dissolved. Hence the recovery of uranium oxide is only partial.

In this connection some experiments were conducted on the conversion of sodium uranate into uranium oxide. In one series of experiments both dry and moist samples of pure sodium uranate were dissolved in a slight excess of concentrated sulphuric acid and then precipitated with an excess of ammonia. After ignition and extraction with dilute sulphuric acid 59 per cent of the uranium was recovered as pure oxide U_3O_8 , and in the case of moist uranate, the recovery was 64 per cent. This process resolves itself into virtually treating the sodium uranate with ammonium sulphate. Another experiment consisted in boiling both dry and moist sodium uranate in concentrated solutions of ammonium chloride, filtering off the precipitates, igniting and treating the residue with dilute sulphuric acid.

In the experiments with the dry sodium uranate by this method, the recovery of uranium oxide was found to be 64 per cent, and in the case of moist sodium uranate, a recovery of 61 per cent was obtained. These experiments show that in one of the commercial methods of converting sodium uranate into oxide approximately 64 per cent of the uranium is recovered, and assuming that 15 per cent of the uranium oxide is dissolved by the acid used in extracting the sodium uranate, it is seen that 75 per cent of the sodium uranate is converted into ammonium uranate.

Treatment of Carnotite Ore with Hydrogen Chloride to Remove Vanadium

Since hydrogen chloride removes vanadium completely from crude sodium uranate, the idea suggested itself of trying the effect of the gas on the vanadium in the original ore, with a view of developing a quantitative method of determining the vanadium in carnotite ores.

A few charges were run at room temperature, but it was found that the removal of the vanadium was far from complete, thus confirming the conclusions of Hille-

brand.² Experiments were next tried by heating the ore while the hydrogen chloride was passing over it. It was found that the yield of chlorides and oxychlorides was much greater, but even in this case, only about one-half of the vanadium was removed. The ore caked rather badly, due to the water formed in the first part of the operation, so it was necessary to remove it from the tube, pulverize it and treat it again with hydrogen chloride.

The experiments which yielded the best results were conducted as follows: the sample of the ore was placed between plugs of glass wool in a hard-glass tube and hydrogen chloride passed over it until no more brown fumes were given off. The hydrogen chloride generator was disconnected then and the ore heated to drive off all moisture present. After this it was removed from the tube, thoroughly ground and mixed with powdered glass in order to let the gas have an opportunity to come in direct contact with each particle of the ore. The sample was replaced in the tube and hydrogen chloride (gas) passed over it for about two and one-half hours, at as high a temperature as could be obtained in the combustion furnace. The residue that remained in the tube was brown and sandy-like in appearance and gave only a very slight test for vanadium. Other experiments conducted under nearly the same conditions failed to give as satisfactory results as the one above did, showing that it is rather difficult to remove the vanadium by this method.

The treatment of the ore by hydrogen chloride for the removal of vanadium has a very direct bearing on the problem at hand. If the vanadium could be removed from the ore by this treatment at the beginning of the process a uranate would be obtained free from vanadium. Moreover, the removal of the vanadium before treatment of the ore for the extraction of radium would very materially simplify the entire process.

Treatment of the Crude Uranate with Chlorine Gas

In connection with the experiments of hydrogen chloride for the removal of vanadium, chlorine gas suggested itself as a possibility. Experiments were tried substituting chlorine gas for hydrogen chloride, but the results were negative. Chlorine gas does not react with the vanadium present in the crude sodium uranate, and only a minute trace of the tetrachloride and oxychloride of vanadium was observed.

Separation of Vanadium by Means of Ammonium Chloride

Inasmuch as hydrogen chloride readily removes vanadium from crude sodium uranate as a volatile product, it seemed worth while to conduct some experiments with mixtures of ammonium chloride and sodium uranate at somewhat elevated temperatures. Under these conditions the partial dissociation of ammonium chloride into ammonia and hydrogen chloride would furnish the constituent to react with the vanadium, and at the same time the ammonia and excess of ammonium chloride furnished favorable conditions for the conversion of some of the uranate into the oxide.

A number of preliminary experiments were conducted to ascertain: (1) quantity of water to have present in the mixture of uranate and ammonium chloride, (2) the temperature at which the reaction should proceed, (3) the amount of ammonium chloride required, (4) the kind of a vessel best adapted for the experiments, (5) the effect of other ammonium salts when added as partial substitutes for ammonium chloride.

Experiments were first conducted by mixing the crude uranate and dry ammonium chloride and subjecting this

²Bulletin No. 70, U. S. Bureau of Mines, 82 (1913).

mixture to heat in a test tube. The ammonium chloride was readily volatilized but apparently no vanadium was volatilized. A part of the uranate, however, was converted into the oxide. Experiments were then tried with the mixtures of ammonium chloride and crude uranate made up to a thick paste by the addition of water. When the paste is subjected to heat the water is gradually expelled, and then as the temperature is increased copious fumes of ammonium chloride are given off, and just as the volume of chloride vapor diminishes the characteristic brown vapors of the volatile vanadium compounds make their appearance and continue to be evolved copiously until the molten mass in the crucible becomes solid. Upon testing the residue obtained in this treatment, it was found to contain only a trace of vanadium.

The experiment was here tried of pouring the molten liquid from the crucible into a beaker containing water, to ascertain whether mere fusion with ammonium chloride would render the vanadium soluble. The melt dissolves almost completely in the water. The solution has a decided green color and gave test for both uranium and vanadium. Evidently this procedure must be included in the list of negative experiments.

Experiments were next conducted to determine the minimum quantity of ammonium chloride required for the nearly complete separation of vanadium by the above procedure. Mixtures of uranate and ammonium chloride in the following proportions were heated: (1) ten parts by weight of ammonium chloride to ten parts by weight of crude uranate, (2) fifteen parts by weight of ammonium chloride to ten parts by weight of crude uranate, (3) twenty parts by weight of ammonium chloride to ten parts by weight of crude uranate. The vanadium was satisfactorily separated only in the case where twice as much ammonium chloride was used as crude sodium uranate.

The experiments were first conducted in iron crucibles, but it was noted that a crucible would not stand more than two charges before it showed holes. Nickel crucibles were attacked fully as badly. Iron test tubes made out of 1½-in. steam pipe capped at one end only withstood two charges. Alundum and porcelain crucibles, however, served the purpose very well, and in the experiments that follow porcelain crucibles were used.

In a few experiments, ammonium nitrate was substituted for a part of the ammonium chloride usually used. This modification did not yield very satisfactory results. While it was possible to remove the vanadium by using a mixture of fifteen grams of ammonium chloride, five grams of ammonium nitrate and ten grams of sodium uranate, the percentage conversion of uranium into oxide in the residue was thereby reduced, as shown in the tabulated data that follow.

As a result of these preliminary experiments the following procedure was adopted: A known weight of sodium uranate, ten grams in most cases, was taken and twice that weight of ammonium chloride added. The mixture is placed in a mortar and pulverized, which at the same time mixes it. The pulverized mixture is then placed in a porcelain crucible and water added until a stiff paste is obtained. Heat is then applied slowly at first with constant stirring to drive off the excess of moisture. Strong fumes of ammonia are noted at this point. As the mass becomes dry it has a tendency to cake, but with vigorous stirring this can be prevented to a large extent. After the water has been expelled the mass begins to fuse and continues to do so until there is a green molten liquid in the crucible. This liquid boils freely with the expulsion of ammonium chloride fumes until the excess of ammonium chloride is driven off and then the brown fumes of the chloride and oxy-

chloride of vanadium begin to make their appearance. They were given off very copiously toward the end of process and especially as the molten mass became solid. Sometimes these brown fumes make their appearance before solidification begins, but usually not. As soon as the volatile products cease to be given off, the crucibles were removed from the flame because further heating of the residue greatly increases the percentage of sodium uranate in the residue.

The black residue from this treatment gives a slight test for vanadium. The percentage of vanadium may be estimated colorimetrically by comparison with standard solutions of vanadium. In this way it was found that the vanadium content of the uranate is reduced from 8.55 per cent vanadium oxide to less than 0.5 per cent.

To ascertain to what extent the uranium is converted into the oxide by treatment with ammonium chloride, several quantitative experiments were conducted. The weight of the residue after treatment with ammonium chloride was first determined by introducing the ammonium chloride and a weighed quantity of uranate mixture in a tared crucible and making a run. From the weight of the residue thus obtained, the ratio of residue to uranate was found to be 0.958.

To ascertain the percentage conversion and the percentage of recovery of uranium, analyses were made of the residues obtained in several experiments. The residue from the crude uranate obtained by treatment with ammonium chloride must consist of a mixture of uranium oxide, sodium uranate, sodium chloride, iron oxide and impurities from the ammonium chloride. This residue was shaken with dilute (1:40) sulphuric acid in excess, which dissolves out the sodium salts of uranium and chlorides, and a small percentage of uranium oxide, leaving a black residue consisting of uranium oxide with a small amount of iron oxide. For commercial use the iron present is usually not objectionable.

Table II shows the results of a quantitative determination made on a portion of the residue, obtained by treating a given weight of crude uranate with twice its weight of ammonium chloride to determine the percentage of recovery of uranium oxide and the percentage conversion.

Column 2 represents the weight of the residue taken from a charge and used for analysis. Column 3 represents the equivalent weight of crude uranate calculated from the ratio 0.958. Considering the crude uranate contains 64.6 (Table I) per cent uranium oxide, the values in column 4 are deduced and represent the total amount of uranium oxide present in the residue. Column 5-a represents the weight of uranium oxide found after treating the residue with dilute (1:40) sulphuric acid. However, it was found, as will be shown later, that this residue is only 95 per cent pure, and thus b represents the weight of uranium oxide actually recovered on this basis. Column 6 represents the amount of uranium oxide present in the residue before treatment with dilute sulphuric acid. Assuming that 15 per cent of the uranium dissolved in the dilute acid used to remove the remaining sodium uranate. Column 7 repre-

TABLE II—RECOVERY OF URANIUM OXIDE

No. of Sample	Weight of Residue	Crude Uranate Equivalent	Total U ₃ O ₈ as Oxide	Weight of Pure U ₃ O ₈	Total Conversion	Per Cent Recovery	Per Cent Conversion
1	0.5918	0.6184	0.3995	a—0.2840 b—0.2692	0.3174	67.4	79.2
2	0.6082	0.6355	0.4105	a—0.2930 b—0.2778	0.3268	67.6	79.6

sents the percentage recovery, figured from the weight or uranium oxide given in b, column 5. Column 8 represents the percentage conversion based upon the values of column 6.

The purity of the uranium oxide removed was determined by dissolving two samples of the uranium oxide residue after treatment with dilute sulphuric acid in nitric acid. The insoluble material was filtered off, and the iron precipitated with ammonium carbonate in excess. The iron was filtered off and the ammonium carbonate solution boiled to expel the excess of ammonia and precipitate the uranium compound, which was then converted to uranium oxide by ignition. In this way it was found that the residue contained 94.8 per cent U_3O_8 .

To ascertain the effect of temperature on the percentage recovery of uranium, an experiment was run in which the final temperature was raised much higher than in the preceding case. Only 58 per cent of uranium oxide was recovered and the conversion was reduced from 79.5 to 68.3 per cent.

To confirm this conclusion a third series of experiments was conducted in which the volatile products were vaporized at still lower temperatures than obtained in the first experiment. The recovery of uranium oxide was raised to 78.5 per cent and the conversion attained the value 92.4 per cent. Hence the lowest temperature possible to remove the vanadium gives the most efficient recovery of uranium oxide.

A quantitative determination was made on the residue obtained by treating ten grams of crude uranate with a mixture of fifteen grams of ammonium chloride and five grams of ammonium nitrate. The vanadium here was removed to less than half a per cent, but the results of the experiment clearly showed that the percentage recovery, 48.8 per cent of uranium oxide, is very materially decreased. While the addition of the ammonium nitrate reduces somewhat the temperature at which the mixture fuses, it is evident its presence materially reduces the yield of uranium oxide.

Separation of Vanadium by Means of Mineral Acids

A—NITRIC ACID

Hillebrand refers¹ to the work of Friedel and Cumenge² on the separation of vanadic acid from carnotite ore by rendering the oxide insoluble in water by evaporating the nitric acid solution to dryness. This method of separating the vanadium from crude sodium uranate was tried, but it did not work very successfully, as a large part of the uranium was rendered insoluble as well as the vanadium, and then, too, the vanadium was not completely removed from the uranate.

Some modifications of this method were then tried, which finally furnished a quantitative method of separating vanadium from the crude uranate. In connection with some qualitative experiments upon the action of nitric acid on sodium uranate, we found that when the vanadium bearing uranate was dissolved in dilute nitric acid and the solution then boiled that the vanadium was precipitated quantitatively.

Quantitative experiments were then conducted to determine the following factors: (1) the proper amount of nitric acid necessary to dissolve the crude uranate, (2) the recovery of uranium from the solution of uranium oxide and its purity, (3) the amount of uranium in the precipitate containing the vanadium.

1. *The Quantity of Nitric Acid.*—By taking weighed samples of uranate and dissolving them in nitric acid of different concentrations and then boiling this solu-

tion to precipitate the vanadium, it was found that acids ranging in concentration from N/20 to N/50 completely removed the vanadium. Boiling of concentrated nitric acid solutions of the uranate results in only partial precipitation of the vanadium. The quality of pure nitric acid necessary for a given weight of crude uranate is given in the table below. It might be stated here that it is only necessary to boil the nitric acid solution for two or three minutes to precipitate the vanadium. It should also be stated that the quantity of nitric acid required is practically that shown by the equation,

2. *Recovery of Uranium and Its Purity.*—The recovery of the uranium from the filtrate of the nitric acid solution is best accomplished by precipitating it with ammonium hydroxide and then igniting the precipitate of ammonium uranate. Some sodium uranate is probably precipitated out with the ammonium uranate, which, upon ignition gives a mixture of uranium oxide and sodium uranate along with a small quantity of iron. The sodium uranate can be easily removed by agitating the ignited residue with cold dilute (1:40) sulphuric acid. The oxide of uranium thus obtained is free from vanadium, and sodium uranate.

It was found on analysis of the uranium oxide obtained after treatment with dilute sulphuric acid that it was about 95 per cent pure. The impurity here is undoubtedly due largely to iron present, which is not objectionable for most commercial purposes.

3. *Uranium Present in Precipitate Containing Vanadium.*—The amount of uranium present in the vanadium precipitate was determined in a manner similar to that used in determining the uranium in carnotite ore except that dilute hydrochloric was used to dissolve the precipitate. Concentrated hydrochloric acid and aqua regia do not dissolve it completely. The analytical data obtained are summarized in Table III. The uranium content given in column 3 was deduced from the analysis given in Table I. Column 4 gives the weight of insoluble residue containing the separated vanadium and the next column shows the weight of uranium oxide present in the residue. The figures in the last column show that about 14 per cent of the uranium is carried down in the residue. The further treatment of this residue for the separation of uranium and vanadium is in progress.

TABLE III.—ANALYSIS OF VANADIUM PRECIPITATE

No. of Sample	Weight of Crude Uranate	Total U as Oxide	Weight of V_2O_5 Residue	Weight of U_3O_8 in Residue	Per Cent U_3O_8 in Residue	Per Cent U_3O_8 of Total U_3O_8
1	2.8270	1.826	0.5728	0.2506	43.7	13.2
2	2.9383	1.898	0.5590	0.2733	48.9	14.4

Next a series of determinations was run to find the weight of pure nitric acid required to react with a given weight of crude uranate, the percentage recovery of uranium oxide and the weight of the vanadium residue. Four determinations were made and the results obtained are given in Table IV. The numbers in the fifth column represent the weights of crude uranium oxide recovered and the next column gives the weights of uranium oxide after treatment with dilute sulphuric acid to dissolve out sodium uranate.

It will be noted from this table that the recovery of uranium dropped considerable in the cases of samples 2 and 4. This result is readily accounted for when the sulphuric acid filtrate (column 6) was taken and analyzed for uranium oxide. In the case of sample 2, 22.5

2					20.2	56.6
3					19.0	65.4
4					21.1	58.6

per cent of the total uranium oxide was found in the filtrate and 25 per cent for sample 4. It will also be noted that the weight of vanadium residue bears an almost uniform ratio to the weight of the crude uranate treated. This method of treatment still leaves approximately 13.5 per cent of the total uranium in combination with the vanadium, but the vanadium is completely removed and 65 per cent of the uranium is recovered as pure oxide.

B—TREATMENT WITH HYDROCHLORIC AND SULPHURIC ACIDS

After obtaining a good separation of vanadium from crude uranate with dilute nitric acid, the investigation was extended to dilute hydrochloric and sulphuric acids. Experiments were conducted very similar to those used in the case of nitric acid, and it was found that here, again, the vanadium could be removed quantitatively with hydrochloric acid, but only in some experiments was the treatment with sulphuric acid successful.

Two samples of the crude uranate of approximately five grams were dissolved in the least possible amount of hydrochloric acid, which had been standardized. The solutions were then brought to a boil and boiled for a few minutes to precipitate the vanadium which settled out very readily. The vanadium residue was filtered off and ammonia added to precipitate the uranium. The precipitate of ammonium uranate was filtered off, ignited to uranium oxide and the residue treated with dilute (1:40) sulphuric acid to extract the sodium uranate present in the ignited residue.

Table V gives a summary of the results obtained in these experiments.

TABLE V SEPARATION OF VANADIUM WITH HYDROCHLORIC ACID

Number of Charges	Weight of Crude Uranate	Total U as Oxide	Weight of Pure HCl per G. of Uranate	Weight of U_3O_8 by Pp't	Weight of U_3O_8 in H_2SO_4 Residue	Weight of U_3O_8 in Filtrate	Weight of V_2O_5 Residue
1	5 7852	3 7383	0 3492	3 3586	2 3864	0 8884	1 0360
2	5 4948	3 5496	0 3712	3 2353	2 4673	0 7078	1 4530
		Per Cent		Per Cent	Per Cent	Per Cent	Per Cent
1		64.63		80.8	63.3	23.8	18.4
2		61.63		91.1	69.5	19.9	22.7

Comparing the percentage of vanadium oxide residues here obtained with those obtained by the nitric acid treatment, it appears that the percentage weight of the vanadium bearing residues averages 20.5 per cent, which is in good agreement with the percentage obtained by the nitric acid treatment. Hence we as-

sume that the vanadium oxide residue is the same in both cases.

It will also be seen, from the table, that the percentage of pure uranium oxide in sample 2 is greater than in sample 1, but, on the other hand, the amount of uranium oxide recovered from the sulphuric acid treatment is less, which accounts for the difference. It thus appears that the two acids serve equally well.

A number of experiments have been conducted with sulphuric acid of different concentrations ranging from fifth normal to fortieth normal following the same procedure as with dilute nitric and hydrochloric acids. Thus far we have met with but partial success. In a few instances out of a number of trials the characteristic brown vanadium bearing precipitate was obtained, and the separation of vanadium was practically complete. The quantity of uranium in the precipitate was found to be practically the same as in the precipitate obtained by treatment with nitric acid.

More frequently, however, when the dilute solution of sodium uranate was boiled a canary yellow precipitate appeared. The quantitative experiments conducted made it evident that a part of the vanadium remains in solution whenever the canary yellow precipitate comes down. If we can succeed in duplicating some of the quantitative results obtained in a few cases the treatment with sulphuric acid would be ideal as the cost of sulphuric acid is considerably less.

Summary of Results

The experiments here described have resulted in at least four methods that have proved successful for removal of vanadium from the crude uranate, which is obtained on a large scale in the plant of the National Radium Institute.

1. By the action of hydrogen chloride gas it has been shown that in time the vanadium is completely removed, leaving a residue consisting of sodium uranate, sodium chloride, uranyl chloride, and the other impurities in the crude uranate.

The uranium may be removed from this residue by either of two methods: (1) By boiling with excess of ammonium chloride, which converts the uranium into ammonium uranate, which may be ignited to uranium oxide; (2) by dissolving the residue in a dilute mineral acid and precipitating the uranium with ammonia, as ammonium uranate, which may be converted into uranium oxide by ignition.

The percentage recovery of uranium oxide, free from vanadium, but containing a small percentage of iron, which is not objectionable for its sale, varies from 59 to 64 per cent.

2. By mixing the vanadium bearing uranate with twice its weight of ammonium chloride and enough water to make a thick paste, the vanadium may be nearly completely volatilized by heating in a porcelain crucible. When subjected to proper conditions of temperature, it is possible to reduce the quantity of vanadium present in the crude uranate from 8.5 per cent to less than $\frac{1}{2}$ of 1 per cent. The ammonium chloride serves the double purpose of converting a part of the uranium present to ammonium uranate, which, upon ignition, yields uranium oxide as well as removing the vanadium.

The percentage of uranium recovered may be regulated very materially by the heat treatment to which the mixture is subjected. Where the residue, after volatilization of the ammonium chloride, is heated to a high temperature, the percentage recovery of the uranium oxide (U_3O_8) is reduced due to the fact that some of the uranium oxide formed in the operation is converted back to sodium uranate.

The highest percentage recovery was obtained where the temperature was not raised any higher than necessary to volatilize the ammonium chloride and vanadium compounds.

In this connection it was found that a mixture of fifteen grams of ammonium chloride and five grams of ammonium nitrate to every ten grams of crude uranate served the purpose of removing the vanadium from the crude uranate just as well as the ammonium chloride alone. However, the percentage recovery of uranium oxide is reduced very materially, as it is only possible to get a recovery of about 58 per cent under the most favorable conditions of temperature. This reduction in the percentage recovery more than counterbalances any advantage that the use of ammonium nitrate might have as a partial substitute for ammonium chloride.

3. The vanadium can be completely precipitated by dissolving the crude uranate in the least possible amount of dilute nitric, hydrochloric and sometimes sulphuric acid, and then boiling the solution. Approximately 13 per cent of the uranium is precipitated out with the vanadium, but the amount is small compared to that which remains in solution. The uranium may be recovered by adding ammonia to the solution containing the uranium, free from vanadium, to precipitate it as ammonium uranate, which may be converted into uranium oxide by ignition.

The percentage recovery of uranium oxide in the case of nitric and hydrochloric acid treatments is found to vary from 58 to 79 per cent. Some uranium is lost in the dilute sulphuric acid treatment of the residue for the removal of the sodium uranate, but this uranium may be recovered from the acid solution by precipitation with ammonia.

Only by one of the above methods is the removal of the vanadium and the conversion of the uranium oxide accomplished in one step. That is the case of the ammonium chloride treatment. In all of the other processes the vanadium is removed by one step and the uranium recovered by another operation. However, it will be noted that the percentage recovery of uranium oxide in all the methods was practically the same.

4. Probably hydrogen chloride (gas) may also be utilized to remove the vanadium from carnotite ores quantitatively, by proper regulation of temperature.

Chemical Laboratory,
University of Missouri,
Columbia, Mo.

The American Smelting & Refining Company's tin-smelting plant in the course of construction at Perth Amboy, N. J., will shortly be finished. The company will receive concentrates from Bolivia by way of the Panama Canal, smelt these in reverberatory furnaces with subsequent electrolytic refining. Some shipments of ore have been held up at the canal, which have delayed operations. Very pure tin analyzing 99.95 per cent has been produced in the experimental plant and it is the intention to make a tin to compete with Straits tin.

Geological Survey Cannot Make Assays.—The United States Geological Survey calls the attention of mining men and others to the fact that it is not equipped for making assays or analyses of rocks, its laboratory being in fact overloaded with official work. Many specimens and samples are received by the Survey, accompanied by requests for such treatment, with which it is impossible to comply. The force of chemists employed is small, and their time is fully occupied by their regular official duties. The Geological Survey has no facilities for making gold and silver assays. The most the Survey geologists can do is to give an off-hand opinion based on a simple examination of the specimens.

The Rubber Industry

BY ANDREW H. KING

It has been said that too frequent association dulls the appreciation and relegates important discoveries and advances to the rank of the commonplace. This statement holds very true about rubber. The most of us have grown up with rubber articles about us all our lives. In fact, our association with this remarkable substance dates from the nursing bottle. Consequently, it is not at all out of the way for us to accept rubber as a matter of course.

No material has yet been found which combines such a degree of strength, elasticity, and wearing power. These properties make rubber especially valuable in manufacturing the various grades of hose—air, water, steam, and oil; belts; valves and other molded articles, and tires of all kinds. A complete list of all the various things made of rubber would be almost infinite.

The first mention of this remarkable substance from a European was by Christopher Columbus, who on his second voyage of discovery (1493-1496) saw the natives of Haiti playing with balls, which he afterward learned were prepared from the gum of a tree. This gum they called *cauchu*, from which the word *caoutchouc* is derived. Highly interesting must this gum have been to the Spaniards. By it they were able, in a crude manner, to waterproof their garments, and thus protect themselves from the heavy tropical rains. They also made the acquaintance of the related substance, *balata*. They found shields made of *balata* impregnated cloth. The same material was used in the preparation of suits which resisted poisoned arrows. In fact, such suits are now to be seen in the Spanish museum at Madrid. This was indeed a fine forerunner of the modern *balata* belt.

The English word rubber was given it by Priestly in 1770, who recommended its use for removing pencil marks. This would likely have remained its principal use had not the discovery of vulcanization been made. Raw rubber is not suitable for proofing garments, due to the narrow range of temperature within which it is elastic but not sticky. Below 10 deg. C. it begins to become hard, and at 0 deg. C. it is brittle. However, it regains its former properties on warming. Above 25 deg. C. it has a great tendency to become sticky, and if heated above 75 deg. C. it becomes permanently tacky.

But in 1839 Nelson Goodyear, an American, made his important discovery of vulcanization. The beginning of the rubber industry dates from this invention. The bicycle craze of some years ago gave it added impetus, and as the cycle went out automobiles came in. It is now an accepted fact that these machines cannot be comfortable without pneumatic tires. It has been estimated that at least 85 per cent of all rubber used in manufacturing goes to tires, and only 15 per cent to mechanical goods. The United States alone uses about 100,000 tons of crude rubber per year. So we see that rubber is an established industry.

The Varieties of Crude Rubber

Schidrowitz divides the important rubber-producing trees into four orders, with the following subdivisions:

- | | |
|-------------------|------------------|
| I. Euphorbiaceae— | 3. Clitandra. |
| 1. Hevea. | 4. Hancoria. |
| 2. Manihot. | 5. Dyera. |
| 3. Sapium. | III. Urticaceae— |
| 4. Micandras. | 1. Ficus. |
| II. Apocynaceae— | 2. Castilleja. |
| 1. Funtumia. | IV. Compositae— |
| 2. Landolphia. | 1. Guayule. |

Hevea, brasiliensis.—This is by far the most important rubber of the whole family. It supplies over 60

FIG. 1—HALF HERRING-BONE SYSTEM

per cent of the total output. It was originally native to South America, where great forests of these trees abound. They are often of great height and girth. From the experience planters have had with Hevea in the East, the age of these trees must be well over 500 years. For these reasons alone they should produce the best grade of rubber. In addition, the method of curing or coagulating the latex, while very primitive, gives a product far superior to that secured from cultivated trees. The Amazon valley is the principal rubber district of South America. Commercial Brazilian rubbers are usually classified as Up-river or Hilands, and Islands. The former is shipped from Manaos, which is about a thousand miles up the Amazon. The latter comes from the City of Para, on the coast. Hilands is sometimes called hard cure and Islands soft cure. The commercial varieties include also Fine Para, Coarse Para, Caucho, Matto Grosso, Peruvian, and Bolivian.

The Hevea brasiliensis has been transplanted to the East Indies. Climatic and soil conditions proved suitable, and the wild rubber tree has yielded to cultivation. Now great quantities of rubber are produced on such islands as Ceylon, Borneo, Sumatra, and on the Malay Peninsula. Many varieties of plantation sheets are on the market.

Manihot glaziovii.—This variety is native to Brazil, but has been planted with success in parts of Africa, where Hevea brasiliensis proved a failure. The most important commercial variety of the species is Ceara or Manicoba.

Funtumia elastica.—This species is native to tropical Africa, and supplies the rubbers known as Gold Coast Lumps, and some of the Congo and Cameroonian varieties.

Landolphia, ovariensis, etc.—These species include various vines and creepers which occur in enormous quantities in Congo and parts of the East and West Coast, and in Central Africa. The vines are ordinarily cut down and the latex secured by bleeding. It furnishes Upper Congo balls, Sierra Lione Niggers, Red and Black Kassai, and Madagascars.

Hancoria speciosa.—This species is native to Brazil

FIG. 2—HERRING-BONE SYSTEM

and central South America. It yields Mangabeira, Pahia, and Matto Grosso.

Dyera costulata.—This supplies the very poor rubbers known as Pontinak, Jelutong or Dead Borneo. They contain but about 15 per cent of rubber, the remainder being resin, dirt and water. This variety comes from parts of the Malay Peninsula, Sumatra, and Borneo. Considerable quantities of it are purified. The resin finds many uses, and is sold under the name Malaysian or Pontinak resin. Formerly the trees were felled and bled where they lay on the ground. This very wasteful method has almost entirely given place to scientific tapping. The rubber extracted from Ponti is very good.

Ficus elastica.—This species is found principally in Asia. Burmah, Java and India are the important districts. It has been planted to some extent in the Dutch and German African colonies.

Castillai elastica.—This variety is indigenous to Mexico, Central America and Peru. It produces Peruvian Caucho, Mexican Strips and Centrals.

Parthenium argentatum.—From this species is obtained Guayule. It is found principally in Mexico and southern Texas. The rubber occurs in the solid state among the woody fibers of the shrub. Guayule found considerable favor in this country until continued revolutions made the gathering of the shrub and the extraction of the rubber at least rather hazardous, if not to say impossible. While the production of Guayule destroys the shrub, it does not seriously cripple the industry, since it grows very fast and was formerly looked upon as farmers regard blackberry bushes.

For 1912 Maclaren made the following estimate, which will serve to show the relative importance of the various grades of rubber. In these figures allowance has been made for the resin content of low-grade rubbers.

Plantations	28,500 tons
Brazil (Amazon Basin)	48,830 tons
Brazil (Bahia)	4,000 tons
Central America	2,500 tons
Africa	20,000 tons
Guayule	3,500 tons
Jelutong	6,000 tons
Total production	113,330 tons

FIG. 3—SERINGUEIRO SMOKING RUBBER AT ALTO ACRE

Basing his figures on the increase in production of plantation rubbers, the decreasing supply of some wild rubbers, and upon the further demand, he estimates for 1916 as follows:

Brazil	15,500 tons
Central America	250 tons
Africa	1,000 tons
Jelutong	500 tons
Plantations	130,000 tons
Total production	147,250 tons

While the figures for 1915 are hardly yet available, it seems that his estimate will at least prove conservative. For 1920 he estimates as follows:

Brazil	2,000 tons
Various	500 tons
Plantations	160,700 tons
Total production	163,200 tons

According to his opinion the cheaper grades of rubber will be gradually eliminated, and there will remain only Brazilian and plantation rubbers. Another factor in driving out the low-grade rubbers is the improved shoddy processes, which furnish cheap and fairly good material. In fact, many rubber chemists prefer high-grade shoddy to some of the low-grade rubbers.

The following figures were taken from an extensive table by Spence, and serve to show the relative values of crude rubbers on the basis of their washing loss and resin content.

Trade Name	Washing Loss,		Resin Content,	
	Per Cent		Per Cent	
Fine Para, Islands.....	17	-20	2	-3
Fine Para, Hilands.....	14	-19	1.6	-3
Plantation Crepe	0.2	-1	1.3	3.6
Caucho	18	-23	3.5	5.5
Manicoba	30	-55	3	6.5
Gold Coast Lump.....	30	-55	7	10
Jelutong	64	-70	70	-85
Guayule	15	-40	20	-25

Tapping

Rubber is derived by a process of coagulation from the latex of certain trees, shrubs, or plants, which have been already discussed. The latex is quite distinct from the sap, and is contained in a separate cell system which lies between the outer bark and the cambium. Obvi-

ously a very thorough knowledge of the lactiferous system is necessary to yield the best results on tapping.

In the Amazon district the old V method is still in use. It consists of a series of V's, the first being about 6 to 7 ft. above the ground, and successive cuts beneath it down the trunk. The next row begins about 18 in. over, and just a little lower than the first one, and so on down the tree. The third row begins with a cut on a level with the first one. Earthenware cups are placed at the apex of each V to collect the latex.

In the plantation districts of the East the half herring-bone method is most preferred. This consists of a series of oblique cuts running into a central channel. See Fig. 1. Additional tapping is done by paring away a strip of bark about 1/4 in. wide along each cut. When a sufficient area is exposed the tapping is transferred to the opposite quarter of the tree. When the allowable area of trunk is exposed on that side, the tree is left to rest for three or four years. Later the tapping is begun on the quarters adjacent to the former wounds. The full herring-bone method also finds favor, and consists of simply twice the area of the half herring-bone. See Fig. 2. The latex is collected in a small iron cup fixed at the base of the central channel. These cups are emptied at regular intervals, and the latex taken to the plantation factory for coagulation. There are other ways of tapping, but these are the most important.

The Nature of Rubber Latex

Latex is a white to cream-colored fluid, resembling milk in appearance. When this emulsion is examined under the ultra-microscope it is found to consist of very minute (0.5 to 4 mu.) oil-like colloidal particles floating in a clear serum. They are in rapid Brownian movement, and when the latex is electrolized they go to the positive pole, thus proving them to be negatively charged colloids.

The liquid is either slightly alkaline or amphoteric in reaction. It contains various enzymes, which if allowed time to act will produce acids, and thus precipitate the colloids. Besides India rubber, the latex contains vari-

ous resins, proteins, and acid salts, such as sulphates, malates, phosphates, and chlorides. Sugars and alkaloïds may also be present. Seelingmann gives the following average analysis of Para latex:

	Per Cent
India rubber	32
Albumenoid extracts and mineral matter	12
Water	56

Coagulation

By coagulation we mean the formation of an irreversible colloidal gel. The colloids coalesce. The particles grow larger and larger, and begin to throw out minute hair-like arms and connect one another. This leads to a reticulated or network structure which is not lost when

FIG. 4A — MICRO-PHOTOGRAPH OF A DROP OF FRESHLY COAGULATED FUNT. ELAS. LATEX, SHOWING RETICULAR STRUCTURE

FIG. 4B—THE SAME AS "A" AFTER APPLYING PRESSURE. NOTE THE ALTERATION IN STRUCTURE. (FROM A DRAWING.)

the sheet is ready for market. Schidrowitz coagulated a drop of latex between a slide and cover glass, and noticed that the reticulated appearance could be intensified and made coarse by working a little and by using slight pressure. Fig. 4 illustrates this phenomena. This gave him an explanation of the effect of working on freshly coagulated latex. Latex coagulated by chemical means appears first as a cheesy mass, which readily gains in strength and cohesiveness on working through the rolls.

Coagulation has been performed by many methods. In this paper I will only discuss those most in use and which give the best results. The market value of a rubber depends much on the care used during coagulation. For example, African rubbers are as a rule very dirty, highly resinous, and of a very foul odor. No care is used in gathering the latex; in fact, many of the savages smear it on their stomachs until they have a good-sized lump, and then peel it off. The heat of their bodies coagulates it.

Probably the oldest and undoubtedly the best method of coagulation is that used in the Amazon country. The "seringueiro" or rubber gatherer first makes a small fire, in which he burns the nuts of the urucuri palm. These nuts give a dense smoke, which is rich in the products of wood distillation, such as creosote, acetic acid, and so forth. Next he places a long pole or mandril over the fire, and pours on it a small quantity of latex. The pole is rotated until a thin film of dried rubber has formed, when he makes another application. The process is repeated until he has a loaf of about 100 lb. Rubber so prepared forms the biscuits of trade, which are easily recognized since the loaf is made up of concentric layers which may be separated. Fig. 3 shows the hut of the seringueiro. There is no rubber better than Hilands Fine Para. The method of coagulation is largely responsible for this, since it allows all

the elements of the latex to be evenly distributed throughout the mass.

On the plantations coagulation is brought about by the addition of a small quantity of very dilute organic acid. Acetic is mostly used, though formic also finds favor. It has become the custom to add a small quantity of sodium sulphide to the latex before coagulating. This acts as a preservative, and prevents enzyme action which would otherwise cause a black rubber. Most of the Eastern sodium sulphide rubber is sold under the name of Ceylon, and is a very nice, white, clear rubber, greatly in favor, if not absolutely essential, to the manufacturer of white articles. The requisite quantity of acid is added, and the latex allowed to stand a short time, during which coagulation occurs. The freshly prepared rubber is worked and washed on corrugated rolls. This removes any serum left in the pores, and also any foreign matter.

At this point it is well to mention that this excessive cleanliness is a detriment to plantation rubber, for it removes certain nitrogenous bodies which greatly influence the time of vulcanization, and thus make necessary the employment of some form of accelerator. Accelerators are used also with Para, but are not nearly as necessary.

After washing, the rubber is sheeted on smooth rolls. It is then dried, either by means of vacuum dryers or by hanging in a loft. When dry it may be smoked. Hardwood is mainly used for this purpose, and it supplies much the same vapors as are used along the Amazon. The object is to disinfect the rubber and thus prevent bacterial action. Rubber so treated is called smoked sheets, and forms a large portion of the plantation output.

Kaye in a recent article gives the following amounts of various acids required to coagulate normal Hevea latex containing 30 per cent of rubber:

Acid	$\frac{N}{10}$ cc. Acid to 100 cc. Latex
Sulphuric	20 cc.
Hydrochloric	9 cc.
Nitric	31 cc.
Acetic	150 cc.
Oxalic	31 cc.
Tartaric	33 cc.
Citric	71 cc.
Formic	20 cc.

He mentions the fact that no matter what acid is used for coagulation, after the process is complete there is always approximately twice the acidity in the case of Hevea latex than one should expect from the quantity of acid used. The increase is thought to be due to phosphoric acid produced by the hydrolysis of some of the protein groups.

Physical Properties of Rubber

As was previously stated, the structure of rubber is reticular. It is this property which makes possible the addition of large amounts of other substances, as is regularly done in compounding. Films of rubber prepared from solutions do not display this structure until treated with sulphur chloride, after which it is quite pronounced.

The specific gravity of clear washed and dried rubber is usually taken as 0.925. On warming, the gravity gradually decreases.

Rubber is not soluble in water, but will absorb as much as 45 to 50 per cent of it. It is insoluble in acetone or alcohol, consequently these solvents are mainly used in extracting the resinous constituents. It forms a typical colloidal solution with benzole, gasoline, chloroform, toluene, ether, etc. Fig. 5 is an ultra-microscopic photograph of a solution of rubber with benzole.

Chemical Properties

This subject is very broad, and not well established. A full discussion is beyond the scope of this paper.

Alkalies.—Neither aqueous nor alcoholic solutions of the alkalies effect it; i.e., below 100 deg. C. Prolonged digestion with ammonia causes india rubber to pass into an emulsion closely resembling the original latex.

FIG. 5—ULTRA-MICRO-PHOTOGRAPH OF A SOLUTION OF RUBBER IN BENZENE

Chlorine.—When chlorine is passed through a rubber solution a white powder having the formula $C_{10}H_{16}Cl_2$ is formed. This is evidently an addition and substitution product.

Bromine.—Bromine forms in the same manner two products, $C_{10}H_{16}Br_2$ and $C_{10}H_{14}Br_4$. The tetrabromide has been suggested as a means for the direct determination of the percentage of rubber in rubber analysis.

Acids.—Hydrochloric acid gas does not act on vulcanized rubber articles when absolutely dry. In the presence of moisture an additional product is formed.

Sulphuric acid when concentrated acts very vigorously, charring and oxidizing it.

Nitric acid, concentrated, attacks rubber energetically, forming first a yellow body which is subsequently decomposed into nitrogen, carbon dioxide, oxalic acid, and a substance of the character of a fat. On prolonged boiling this is converted into a mixture of camphoric and camphoronic acids.

Nitrous acid, when carefully prepared by running concentrated sulphuric acid into a 20 per cent solution of sodium nitrite and carefully dried by passing the gas through drying tubes containing phosphorous pentoxide, then passed into a solution of dry rubber in water-free benzene, a product having the formula $C_{10}H_{14}N_2O_4$ is formed. This is the rubber nitrosite, and is an amorphous, yellow compound which is insoluble in most of the ordinary solvents, but fairly soluble in dimethyl oxalate. This product has also been suggested for the direct determination of rubber.

Dry Distillation.—On dry distillation of purified Hevea, Weber obtained the following:

	Per Cent
Isoprene	6.2
Dipentene	4.6
Heveene	1.7
Polyterpenes	26.8
Carbon residue	1.9
Mineral residue	0.5
Loss (water and gases)	1.4

The Rubber Hydrocarbon

When commercial rubber is highly purified, it is found to consist almost entirely of a substance having the empirical formula $(C_5H_8)_n$ or $(C_{10}H_{16})_n$. The latter one is most accepted.

Commercial rubber also contains about $3\frac{1}{2}$ per cent of a so-called "insoluble" constituent. Before Weber's study of the subject and his determination of the correct amount, it was thought to supply the strength, while the true rubber hydrocarbon gave the elasticity. Weber easily disproved this theory, and showed it to have the formula $C_{10}H_{16}O_{10}$. He suggested that it forms a link between rubber and the complex carbohydrates, as the celluloses, which he considers the raw material from which the plant produces all the terpenes, includ-

ing rubber. He illustrates his theory by the following reaction:

Harries, on the basis of his work on rubber ozonides, regards it as polymerized 1:5 dimethyl cyclo-octadiene

Rubbers obtained from different sources are not always identical in structure. Harries found that while ozonides of purified Hevea gave on hydrolysis mainly laevulic aldehyde and laevulic acid as a secondary product, the reverse was true of the ozonides of gutta percha, which also has the formula $(C_{10}H_{16})_n$, and of certain African species. His explanation is that the ozonide complex occupies a different position relative to the plane of the eight-ring space, a cis position in one and a trans in the other.

Pickels has suggested that this behavior be explained on the assumption that the rubber hydrocarbon does not consist of a number of polymerized $C_{10}H_{16}$ rings, but of a single ring containing a number of unsaturated C_5H_8 nuclei.

Synthetic Rubber

The production of synthetic rubber has long been the dream of the organic chemist. The conquest of alizarin and indigo gave him confidence to attempt this most difficult task. Synthetic rubber has already been produced, but not in quantities, nor at a price that can compete with the natural product. For synthetic rubber to be an assured success it must be cheap. It has been said that rubber can be laid down in this country from the East at 20 cents a pound should occasion demand it. The rubber grower has allied himself with the botanist, and each year he is strengthening his position. However, should cheap synthetic rubber come, we may well expect the rubber streets that have been predicted.

The beginning of the attempt to synthesize rubber dated from the researches of Harries into the nature of the rubber hydrocarbon. According to his theory, two molecules of isoprene polymerize to 1:5 dimethyl octadiene and this is further polymerized n times to rubber.

Natural rubbers seem to be derived from isoprene, but for simplicity and logic the synthetic chemist begins with butadiene, also called divinyl or vinylethylene $CH_2 = CH - CH = CH_2$, since isoprene is but B methyl butadiene $CH_2 = C(CH_3) - CH = CH_2$. One fact seems already proved. Whenever the grouping $C:C:C$ can be obtained in a compound that compound is capable of being polymerized to rubber. By making substitutions in the butadiene hydrocarbon, it should be possible to secure a whole series of rubbers.

Two molecules of butadiene polymerize as indicated:

In accordance with the above, dipropylene rubber should be formed:

Thus we see that the first part of the problem is to make butadiene or its homologues cheaply. The second part is to efficiently polymerize this substance or substances to rubber. The solution of the second part is already nearly complete, but the first still seems difficult.

The following methods have been proposed for the production of butadiene and its homologues:

From Phenol

Hofman has used the method of synthesis outlined below. For butadiene he begins with phenol, and for isoprene he starts with paracresol. The reactions are identical, so I will indicate only those for butadiene.

By Fermentation From Starch

Fusel Oil Route.—Fernbach has developed a form of bacteria which is capable of producing about 42 per cent of fusel oil from starch. By varying the conditions of fermentation he claims he can produce fairly large quantities of acetone as a by-product. The butyl alcohol of fusel oil is separated and purified. The steps in the process are indicated below.

By using iso-amyl alcohol, which forms a large percentage of the fusel oil obtained from cereals or potatoes, in place of butyl alcohol in the above indicated process isoprene can be obtained.

Acetaldehyde Route.—Perkin in his synthesis also begins with starch, which he ferments to ethyl alcohol by means of yeast. This is converted to acetaldehyde. From this he obtains aldol, which is converted to butadiene by the steps which are indicated below. He claims that this method, when fully developed, will produce rubber at as low as 15 cents per pound.

From Turpentine

The isoprene lamp has long been known. Harries and Gottlob prepared isoprene by its use quite early in

their researches. It consists of nothing more than a flask, in which is suspended just below the neck a platinum coil, which is electrically heated to incandescence. The turpentine or other liquid is boiled in the flask. The vapors are decomposed by the coil and the isoprene is separated by fractionation. Herty and Graham obtained 5.5 per cent isoprene from spirits of turpentine in this manner. By trying the different fractions of commercial spirits of turpentine, they concluded that this is mostly due to pinene and not to dipentene, as was claimed by Harries and Gottlob.

By the use of the isoprene lamp, Harries and Gottlob also obtained as high as 50 per cent isoprene from commercial limonene. Since the volatile oil of pinus serotina contains considerable limonene, Herty and Graham used it in place of turpentine in the isoprene lamp. They obtained a yield of 12 per cent isoprene.

Turpentine as a raw material is too expensive for any of these processes to be a decided success.

Pyrogenic Reactions

Some very excellent work has been done by Kyriakides on this side of the water. His process is essentially one of dehydration. For example, one method for the preparation of butadiene is as follows: beta-butylene glycol is slowly dropped into a tube containing pieces of ignited kaolin heated to 380-400 deg. C. Butadiene is obtained. The dehydration, he thinks, takes place thus:

The reader is referred to his original work, as published in the *Journal of the American Chemical Society*, Vol. 36, pages 530, 657, 663, 980, 987.

From Petroleum

Petroleum has been suggested as a source of butadiene, and its homologues, since by careful fractionation isopentane, $(\text{CH}_3)_2\text{CH}-\text{CH}_2\text{CH}_3$, can be obtained. This may be converted to isoprene by the following steps:

The above are the principal published methods for the production of butadiene and its homologues.

As before stated, the second part of the problem consists in efficiently polymerizing these substances to rubber.

Tilden was the first to discover that isoprene could be converted to rubber. In 1882 he examined a tube of isoprene which had been sealed and set aside twenty

years previously. He was surprised to find its contents no longer liquid. This substance he took to be rubber. It has been said that he did not sufficiently prove that his product was rubber, however there seems to be no doubt that he was right.

If isoprene is spontaneously converted to rubber as the above would indicate, then catalysers which would hasten the reaction should exist. This fact led to the trial of many substances, such as acetic anhydride, hydrochloric acid, etc. Different observers at times obtained polymerization products, but on the whole their experiments could not be satisfactorily duplicated by others.

However, in 1912 Matthews tried the action of sodium wire on isoprene, and was successful. He used about 5 per cent of sodium and kept his sealed tubes slightly warm. This discovery proved to be the key to synthetic rubber, for it provided a rapid, cheap and efficient method of polymerization.

A "seeding out" process has been developed by the chemists of the Bayer company. By it isoprene is heated in an autoclave, where spontaneous polymerization takes place. The process is said to yield a clear white rubber which can be vulcanized.

Vulcanization

By vulcanization we mean the change which takes place when rubber and sulphur are heated together, or when rubber is treated with a dilute solution of sulphur monochloride. The first is called hot vulcanizing and the latter cold curing, which is the word given to this change by rubber chemists. The early investigators of vulcanization called it simply the "change."

Hot Vulcanizing.—In 1839 Goodyear discovered that by treating mixtures of sulphur and rubber at high temperature, the range of temperature within which rubber retains its elastic and non-sticky properties was considerably increased over the crude form. He later also discovered ebonite, which is the end product of the reaction between sulphur and rubber.

Broadly speaking, normal soft vulcanized rubber contains from 2 to 4 per cent combined sulphur, that is, sulphur not extractable by solvents such as acetone. Hard rubber, or ebonite contains from 20 to 30 per cent combined sulphur. The maximum 32 per cent is seldom obtained in commercial ebonite, due to the extended length of time of heating and the large excess of sulphur necessary.

The action of sulphur with rubber seems to be partly physical and partly chemical. It is an addition process, either by adsorption or by straight chemical addition, or what is more probable, by both. It is not by substitution, as was originally thought.

The amount of sulphur which enters into combination with rubber, that is, the combined sulphur, increases with time and rise of temperature. The combination is not a linear function but shows certain jumps at more or less regular intervals. Of these jumps Weber says that they may be taken as probably indicating a particular physical rather than some definite chemical condition of the vulcanized product. His reason is that by curing at different temperatures the jumps occur at different places. Axelrod, on the basis of his experimental work, concluded that vulcanization consists of two separate processes. First, the action of heat on rubber which tends to de-polymerize it; and second, the entry of sulphur into the molecule, thus tending to increase the molecular complexity. He arrived at the conclusion that when de-polymerization due to heat has proceeded so far, the material is in favorable condition for a fresh sulphur attack, and at such points a jump occurs in the curve.

If temperature and time are kept constant, the amount of sulphur entering into the molecule is dependent on the quantity originally present. Weber noticed the fact that articles containing less than 2 to 2½ per cent combined sulphur did not appear vulcanized. Therefore, he concluded that this amount of sulphur is necessary to produce the first of a series of compounds called by him polyene sulphides. This closely approximates the formula $(C_{10}H_{16})_{10}S_2$. By using varying large amounts of sulphur he obtained ebonites which all showed approximately 32 per cent combined sulphur, which would indicate another compound with the empirical formula $C_{10}H_{16}S_2$. He concluded that there exists a whole series of vulcanized bodies, of which $(C_{10}H_{16})_{10}S_1$ is the lowest, and $C_{10}H_{16}S_2$ is the highest.

Erdmann has brought forth rather an interesting idea. At 160 deg. C., which is practically the upper limit of vulcanization temperatures, melted sulphur contains a large proportion of thiozonide, S_3 , molecules. Since thiozonide readily polymerizes to an eight-ring complex, it is highly probable that this ring would unite with another eight-ring such as rubber is supposed to be. This would give a rubber thiozonide corresponding to the well-known ozonides.

Wolfgang Ostwald has suggested that vulcanization is a physical proposition only, based on the adsorption of sulphur by the rubber colloid.

At present the consensus of opinion of American chemists seems to be that vulcanization is both a physical and chemical change, and that the adsorption of sulphur while actually taking place, is only a secondary matter.

Cold Vulcanizing.—In 1846 Alexander Parks patented the second method of securing the "change." He immersed his samples in a 2½ per cent solution of sulphur monochloride, S_2Cl_2 , in carbon bisulphide. Of late carbon tetrachloride has been used instead of carbon bisulphide with equally good results, and with far less danger. The cold vulcanizing solution is called curing acid in the trade.

The process is only applicable to articles of less than 4 mm. thickness, since before the "acid" could penetrate to the interior, the surfaces would become hard and brittle, "burnt." The cold process finds considerable favor in the vulcanizing of thin goods, such as surgical gloves, etc. It is used quite extensively in combination with rubber cement, and to some extent in curing proofed articles, such as raincoats. The compound formed by cold vulcanization is chemical, and is believed to have the formula:

A method of enameling iron, which may find application in the laboratory by reason of the simplicity of the procedure, is described by M. P. Wood in his work on Rustless Coatings. The metal is first pickled in hydrochloric acid to free it from foundry scale, then washed thoroughly and dried. The first coating applied is composed of 34 parts silica, 2 parts soda and 15 parts borax, mixed in water. The metal thus coated is exposed for 10 or 15 min. in a dull-red-hot retort. A second coating is then applied, consisting of 34 parts feldspar, 19 silica, 24 borax, 16 oxide of tin, 4 fluor-spar, 9 soda and 3 salt-peter. This mixture is first melted in a crucible, then ground to a fine paste in a little water and applied with a brush. The coated piece is then again subjected to white heat in a muffle. It is claimed that the enamel unites with the iron and that pipes thus enameled have been in use for many years without deterioration.

Hydrometallurgy of Zinc and Lead in 1915

A Contribution from the Department of Metallurgical Research, University of Utah, D. A. LYON, Metallurgist in Charge, O. C. RALSTON and J. F. CULLEN, Assistant Metallurgists

The year 1915 witnessed the installation of a great number of semi-commercial plants for the treatment of zinc ores by leaching methods, with subsequent electrolysis of the solution in order to obtain metallic zinc. Practically all of these installations have been in the nature of experimental plants.

When the European war started there were three electrolytic zinc plants in Europe supposed to be operating on a commercial scale. All of these were on a small scale, and were producing zinc from by-products. At Winnington, Northwich, Cheshire, England, was the plant of Brunner, Mond & Co., which is an alkali works and which has been disposing of calcium chloride solution wastes by leaching zinc ores with them (with simultaneous action of carbon dioxide). This gave a zinc chloride solution from which the zinc was recovered by electrolysis, giving a spelter containing 99.96 per cent Zn., and producing chlorine gas which was absorbed to make bleaching powder. This process is one of those originally designed by Hoepfner, and was experimented on during the 90s in Germany, resulting in the installation of a like plant at Duisburg, Germany. Both of these plants have kept secret the exact details of the process by which they have been able to get good zinc deposits as their pure spelter has been for years at a premium of at least 1 cent above the ordinary market price.

In 1914, a plant was built for treatment of zinc carbonate ores at Kristiania, Norway, under the direction of Borchgrevink, and another at Balestrand, Sogn, Norway, under the direction of E. A. Ashcroft, to treat flotation concentrates from Broken Hill. So far as we know, nothing has been heard of these plants since the war began.

In the United States and Canada, however, a great deal of experimental work has been done on the leaching of zinc from ores with its subsequent electrolysis. Nearly all of this work has been sulphuric acid leaching followed by the electrolysis of the zinc sulphate solution. While all the various plants have this much in common, the details of the work varies at most of them by almost as many methods as there are plants.

The Anaconda Copper Company perhaps has gotten farther along with this work than have most of the other companies. They now have a 25-ton plant nearing completion. By a 25-ton plant is meant one that will produce 25 tons of metallic zinc per day. The Anaconda metallurgists regard this as only an experimental plant. Some splendid work has been done at Anaconda in their research work in connection with the development of the process which they are using and the publication of the details of this work by Mr. Laist and his associates will be keenly awaited by those interested in this line of work.

As to the general outline of the processes employed at the various plants at Trail, B. C., and at Anaconda, the electrolytic liquor containing sulphuric acid, regenerated by electrolysis with insoluble anodes, is used for leaching the ore. The ore is a roasted complex sulphide of lead and zinc carrying silver, some gold (and some copper in the case of Anaconda). By the use of barely sufficient acid to dissolve the zinc, it is possible to get a solution of zinc sulphate carrying low amounts of the other constituents of the ore. This solution must be cleaned by the use of zinc oxide, lime or other cleaning agents, and is then electrolyzed. At most of the plants, lead anodes are used in the electrolytic

tanks in order to regenerate sulphuric acid. The process as thus outlined is old, but the refinement of detail has been the feature of nearly every plant attempting to use it.

At Murray, Utah, and Omaha, Neb., are small plants recovering zinc electrolytically. The one at Murray is following the practice as developed at Anaconda, with variations made necessary by local conditions. It is only an experimental plant and it is expected to produce about 2 tons of zinc per day. The Omaha plant is working on zinc oxide material from the refining of argentiferous lead by the Divine process, and is also in the nature of an experiment.

Perhaps the most extensive research work on the leaching and electrical precipitation of zinc has been carried out on the ores of the Bully Hill mine, Shasta County, California. The process for the Bully Hill ore was worked out on the assumption that a good deposit of zinc cannot be obtained from a solution containing much sulphuric acid and the effort has been to neutralize the acid as fast as it is formed at the lead anodes. In treating the Bully Hill ore, lime is used to precipitate zinc hydroxide and calcium sulphate from the solution of the zinc sulphate. This precipitate is suspended in the zinc sulphate liquor of the electrolytic cell and as fast as sulphuric acid forms it is neutralized by the zinc hydrate.

The Reed Zinc Company whose plant is at Palo Alto, Cal., has operated on the bag house dust from the Kennett smelter of the U. S. Smelting, Refining and Mining Company. This is also an experimental plant designed to produce about a ton of zinc per day. Instead of a solid lead anode they use a sponge lead anode resembling the electrode used in a storage cell. As fast as sulphuric acid is formed at this anode it combines with the lead, forming lead sulphate. This lead sulphate can later be used to give up the acid by reversing the current, after placing the electrode in a sulphuric acid solution. The solution for electrolysis is prepared by dissolving zinc sulphate crystallized from the leaching liquor.

At Silverton, B. C., the Standard Silver Lead Mining Company is also experimenting with the production of electrolytic zinc by the French process. French was probably the first man to use manganese in the electrolysis of zinc sulphate solutions, although its beneficial effect has been noticed by other investigators. He found that it deposits as dioxide on the anode and can be redissolved in sulphuric acid and used over again. He operates his process with considerable of the manganese sulphate in his electrolyte, and instead of using sulphuric acid for leaching, uses a solution of by-product sodium bisulphate.

At Welland, Ontario, the Weedon Mining Company is also said to be meeting with success in operating the Watts process. This process proposes the use of a solution of zinc sulphate for an electrolyte in electrolysis, the depolarization of the anode and the prevention of the formation of sulphuric acid by the use of any solid compound of zinc which does not contain objectionable impurities, such as zinc oxide, or blue powder. The fundamental idea of this process is the same as has been worked out in the treatment of the Bully Hill ore. It is also brought out in the recent patents of O. Best of Oakland, Cal.

At Mt. Read on the west coast of Tasmania, it has been reported that the Tasmanian Metals Extraction Company erected a plant for the treatment of zinc-bearing ores, producing a concentrate of zinc oxide. Nothing of the details of the process has been given out, but the zinc is doubtless precipitated from solution by a solution of some alkali, and the resulting hydrate calcined to oxide.

It is noticeable that most of these plants are treating complex ores of lead and zinc, and usually they are sulphide ores. There is a great amount of "complex sulphides" available in various mining districts and much of it has resisted all efforts at separation. Most of the lead smelters are receiving ores with a considerable zinc content and the zinc causes them to operate at a great handicap on account of the difficulty of fusing the zinky slag and due to the fact that a large amount of lead and silver is caused to go into the slag. Most of these smelters have been looking around for ways and means of removing this zinc before the ore goes into the blast furnace and there is no doubt that the removal of the zinc will allow much more economy in the lead smelting. For example, it is stated that one of the smelters in the country has concluded that even if zinc costs 7 cents per pound for removal and sells for 5 cents, the operation will still allow them latitude enough in the operation of the lead smelter to make the process slightly profitable. It is also stated that the Anaconda plant expects to produce zinc for 4 cents or even less. It is doubtful if small plants can produce zinc at such a low cost and it is also doubtful if it is possible at the present time to install a small electrolytic zinc plant which will be a paying proposition. In order to produce zinc cheaply electrolytically, extraordinarily cheap electric power is a very important item. Moreover, the plant must be comparatively large and this means that only the larger companies would at the present time be warranted in producing zinc in this manner, as this cost of installation is too great except for the large companies.

In other words, it now looks as if the production of zinc electrolytically is not a "poor man's proposition" for the reason that installation costs for a plant which will make money are liable to run well into the millions. However, as the work progresses, it may be found that this is not necessarily true.

The complex sulphides are, of course, being roasted before treatment, and it is worthy of note that most of the experimental work is being done with McDougal and Wedge furnaces. The roasting takes a considerably longer time than does the roasting in ordinary lead smelting and there is some question as to whether this type of furnace will do the work satisfactorily. Zinc smelters have used Hegeler and other like furnaces in which the time of roasting is as much as sixty hours, while most Wedge and McDougal furnaces are so constructed that the ore will travel through the furnaces in four hours, but can easily be slowed down to eight. Whether this type of roaster will meet the requirements or not is still a question.

Very little has been done with the carbonate ores which carry zinc, although it is understood that most of the smelters in Utah have experimented with the leaching of these ores. The Salt Lake station of the Bureau of Mines in connection with its work on the low-grade and complex ores has been doing work along this line and finds that most of the carbonate ores yield up their zinc readily. Very little has been done on the electrolytic deposition of the zinc in the solutions obtained by leaching these ores with sulphuric acid. The carbonate problem is not as pressing as is the mixed sulphide problem, for the reason that in most districts the sulphides constitute the main ore, and furthermore, the carbonates of lead which are found in most districts are not as seriously contaminated as are the zinc ores, for the reason that in the weathering process the lead carbonate resulting from galena does not travel far from the original galena while the zinc carbonates are often found at considerable distances from the original position of the sulphides. However, there are plenty of instances of mixed carbonates of lead and zinc that defy

treatment, and being carbonates they have been let alone whenever it was found that they were complex, due to the fact that very few instances are known where they could be mechanically separated.

All things considered, it would seem as if a very decided advance had been made in the hydrometallurgy of zinc during the year 1915 and while the total amount of metallic zinc produced to date by electrical precipitation has been small, and at present commands a premium as "brass special," it will probably not continue to do so long, due to the large amount of it which will be produced by new plants now being installed or contemplated.

Lead

The hydrometallurgy of lead has received serious consideration during the past year. Inasmuch as it is sometimes found difficult to leach copper ores at a profit, it may seem strange that any one would even consider leaching an ore for such a low-priced metal as lead. However, if we compare the atomic weights and chemical equivalents of copper and lead, it will be seen that the quantity of chemicals required to extract a pound of copper should extract $3\frac{1}{2}$ lb. of lead. Counting lead as worth 3 cents to the producer in the mountain region, the net result of the use of the chemicals which extract 1 lb. of copper will be 11 cents worth of lead. Although such a comparison looks favorable when made in this manner, the difficulty has been to find a suitable solvent for lead.

The Bureau of Mines station at Salt Lake City in its work on the recovery of lead values from the low grade lead ores made a study of the results obtained in three different mills during 1914 and found that the possibility of leaching lead was not at all discouraging. For example, at the mill of the Mines Operating Company, in Park City, the superintendent, Mr. Holt, found that his brine solutions built up to 8 lb. of lead per ton. He was giving his ore a chloridizing roast and then leaching with a 20 per cent salt solution. This was extracting the copper, gold and silver of his ore. Some of the lead precipitated on the scrap iron which was used for removal of the copper from the solution, but this was only a small part of the lead in his ore.

At the Knight-Christensen mill in Silver City, it was also noticed that lead was soluble in the brine solution and steps were being taken to recover this lead when the mill burned down. They had been very successful in recovering it on a laboratory scale by electrolysis of the solution.

The Bunker Hill and Sullivan mill at Kellogg, Idaho, had also been trying out a chloridizing process on some of the portions of their ore which had resisted concentration. The Malm process was used but was abandoned when it was found that there was not enough zinc in the ore to allow economical treatment of the ore in question, as the Malm process depends upon step precipitation of the various metals in solution until finally a solution of zinc chloride is left which is evaporated and electrolyzed. If the zinc is not present in the ore, it must be added.

During the experimental work on the Malm process, some observations had been made on the effect of brine solutions on chlorinated ore, which finally led to the conclusion that most of the galena of the ore, even in an atmosphere of chlorine, was being converted largely to sulphate of lead, and that this sulphate of lead was soluble in a saturated brine. This was checked up by direct experiment and proved to be a most useful fact in the further development of a process. The brine had been used due to its known solvent power for silver chloride and lead chloride. Earlier in their work the Malm company had found that the solubility of lead

chloride in saturated solutions of salt is considerably increased over that in water, due doubtless to the formation of a double salt, and since they did their work, the solubility of the $\text{PbCl}_2\text{-NaCl}$ system has been published in the *Compt. Rend.*, confirming their results. At the plant of the Bunker Hill and Sullivan company it was found that the lead had been extracted from the Bunker Hill and Sullivan ore due to the fact that the sulphate of lead was also soluble in the brine.

With these facts in mind, Mr. Handy of the Bunker Hill and Sullivan company decided to try roasting the ore with a small amount of salt, in order to chloridize the silver of the ore and allow the lead to either chloridize or to form sulphate as it pleased. This left the ore in a condition such that all of the lead and much of the silver was soluble in a saturated solution of common salt.

In co-operation with the Bunker Hill and Sullivan company, the Salt Lake station of the Bureau of Mines took up the investigation of this process at this point. Under the direction of C. L. Larson, who at that time was connected with the Metallurgical Research Department of the University of Utah, an investigation was made of the possibility of applying the Holt-Dern roaster to the chloridizing of the Bunker Hill and Sullivan ore. Exclusive of the salt, this roaster had shown a cost of 16 cents per ton for roasting, at the mill of the Mines Operating Company at Park City, Utah. The Bunker Hill and Sullivan ore only contained 4 per cent sulphur, but Larson was able to roast it without the addition of fuel, and at the same time he got good extractions of the lead upon leaching with brine. As to the details of the process, which has been developed by the Bunker Hill and Sullivan company, these will be given to the public at such a time as may suit the convenience of the company. In the meanwhile, an experimental plant is being operated to collect data on the best temperature of the solution to use and to work out other data necessary for installing the process on a commercial scale.

The Bureau of Mines is now attempting to apply this process, without roasting, to the carbonate ores of lead. In doing so, it has been found that most of such carbonate ores yield their values to a saturated brine solution containing enough sulphuric acid to convert the lead to soluble sulphate or chloride. Natural sulphates of lead, while somewhat rare, and always accompanied by carbonate, will dissolve in the neutral brine. On running in cycles it has been found that sulphate of sodium or any other sulphate does not accumulate in the solution but seems to stay behind in the ore, due to the fact that sodium sulphate is not very soluble in a saturated brine. Consequently, as many as thirty complete cycles have been run without deterioration of the solution.

Following up Christensen's work, it has been found that the electrolysis of brine gives a spongy lead. Unlike any other spongy metal deposited from solution, it is perfectly feasible to melt this sponge lead into bars without serious oxidation and even when it does oxidize to some extent a very small amount of reducing agent will reduce the lead with ease. Such a thing is not possible with copper or zinc sponge. Furthermore, with the use of an iron anode, iron will go into solution, thus lowering the operating voltage, so that with a current density of 69 amp. per square foot at the cathode, only half a volt is necessary, and the solution can be almost stripped of lead before the current density must be reduced. Under these conditions the almost unbelievable amount of 70 lb. of lead per kilowatt-hour can be removed from the solution as a sponge which settles into the bottom of the cell where it can be compacted and

removed to be melted down. Furthermore, this spongy lead will not short-circuit the electrodes and hence the cells can be operated without much care. The iron going into the solution does not seem to affect the purity of the lead melted down and does not build up in the solution to much more than 1 per cent, some of it seemingly remaining in the ore.

The future of such a process is hard to predict but with such a great amount of mill solvent as the Great Salt Lake contains, it would look as though the low-grade carbonates of lead in Utah might be profitably treated by leaching instead of by furnacing. At least they could be concentrated into a 70-80 per cent product before going to the furnaces, and with a high extraction of the metal. Lead carbonates often have a bad tendency to slime and be lost in the tailing of a concentrating mill, but slimes need not interfere with a process of this kind. With several mills testing out the process, the developments in 1916 will doubtless be of considerable interest, both technically and commercially.

The Cost of Flotation

In a paper presented to the A. I. M. E. by J. M. Callow, the author gives the following data on the cost of flotation as practised by his pneumatic process, which was described in this journal Sept. 1, 1915:

Oil.—The oil mixtures generally in use cost from 1.25 cents per pound up to 3 cents per pound, depending on the percentage of creosol and other higher-priced oils used; on most ores $1\frac{1}{2}$ cents per pound is a safe average figure, and a consumption of 1 to $1\frac{1}{2}$ lb., or from 1.25 cents to 4.5 cents per ton of feed, averaging $2\frac{1}{2}$ cents, would be a safe estimate.

Labor.—This will vary, of course, with the size of the plant. At one plant, consisting of 60 cells, two men per shift operate the entire plant, equivalent to a cost of $1\frac{1}{4}$ cents per ton. One man per shift on a 250-ton plant means a cost of 5.4 cents per ton maintenance. Assuming a life of three months per blanket, a capacity of 50 tons per cell, and an allowance for repairs to blowers, motors, pumps, etc., we have $\frac{1}{2}$ cent per ton as a liberal allowance.

Power.—With power at 1 cent per kilowatt-hour, and a consumption of $2\frac{1}{2}$ kw-hr. per ton, the cost would figure 2.5 cents per ton of feed.

Summarized, the estimated cost on a 2000-ton flotation plant, or larger, would be approximately as follows:

	Per Ton, Cents
Labor	1.25
Oil	2.50
Maintenance	0.50
Power	2.50
Total	6.75

On a plant of 250 tons the extra labor costs per ton would bring it up to approximately 10 cents per ton of flotation feed.

Actual figures from a large plant treating over 2000 tons by flotation gave 6.1 cents per ton; the flotation feed in this case represents 60 per cent of the crude ore tonnage, making the cost 3.5 cents per ton of crude ore treated.

Byproduct Coke Oven Plant.—The Indiana Coke & Gas Company of Terre Haute, Ind., has placed a contract with the Gas Machinery Company of Cleveland, Ohio, for a byproduct coke-oven plant, consisting of thirty cross regenerative byproduct coke ovens and apparatus for the recovery of tar and ammonia. Indiana coal will be used and the coke will be sold, for the time being, for domestic uses. The surplus gas will be delivered to the Terre Haute Gas Company for local consumption.

A Form for the Classification of Flotation Data

BY W. A. WHITAKER AND GEORGE BELCHIC

The increasing importance of flotation as a method for ore concentration and mineral conservation is illustrated by the fact that many private corporations, as well as university laboratories, are now engaged in investigating this process. Most of these investigators have as their object the defining of the conditions necessary for successful flotation when applied to particular material, while others are engaged in purely theoretical work looking toward an explanation of the various phenomena upon which flotation is based. Whatever the object sought, the investigation, if prosecuted to any extent, will result in the accumulation of a large amount of minute data, which unless arranged in such a way as to allow of ready comparison and correlation, may soon become a mass of unwieldy material, difficult of clear interpretation.

In order to compile in a condensed arrangement the results obtained in this laboratory and thus allow of quick and easy comparison and correlation, the form

illustrated below was evolved and printed in quantity. With this arrangement, the investigator has before him on one sheet (1) the screen analysis, (2) the assays, (3) the charge used, (4) the derived data, and (5) the plotted efficiency of the frothing agent.

The same form may be used also when the effects of other flotation factors are being investigated, such as variations of temperature, duration and speed of agitation, quantity of acid, etc. This condensed scheme has worked so satisfactorily in this laboratory, it was thought that its publication might be helpful to those who are beginning investigations on flotation and possibly to those already launched upon the subject.

Reverberatory Smelting at Consolidated Arizona Smelting Company, Humboldt, Arizona

(Editorial Correspondence)

In a previous article in this journal¹ we described in detail the concentration of copper ores by flotation at Humboldt, Ariz., and gave many valuable data on the method and cost of operation. In conjunction with the concentrator, the company operates a smelting plant for the treatment of its own ores and concentrates and certain ores bought on a custom basis. The custom business is being built up as rapidly as the development of the district warrants. Smelting is done in oil-fired reverberatory furnaces, and copper is produced from matte in basic-lined converters. Production has averaged about 500,000 lb. of blister copper per month, two-thirds to three-fourths of which is from company ore and the balance from custom material. Costs of operation and production will be officially announced by the company in the near future.

The equipment of the plant consists of one seven-hearth Wedge roaster, 21 ft. 6 in. diameter, fitted with auxiliary oil burners; one 19-ft. by 60-ft. and one 19-ft. by 100-ft. reverberatory furnaces, the latter being under construction and practically completed at the time of writing, and two 9-ft. 6-in. diameter barrel-type basic-lined converters.

Table I gives in condensed form average analyses of some of the materials treated and products made. Gold

and silver are indicated in ounces per ton and the other constituents in per cent.

In addition to the company's own products, a considerable tonnage of custom ore is treated, a large portion of this being a copper-bearing specular hematite containing 43 per cent iron and 10 per cent insoluble. Converter flux and fettling material is highly silicious copper ore from the upper levels of the company's mines, and contains 3.8 per cent copper and from 70 per cent to 80 per cent insoluble. In this ore the copper minerals are more or less oxidized and not well suited to concentration, particularly flotation, tending to "kill" the froth in the latter process.

It will be noted that all material entering the plant at any stage of the process is copper-bearing. Barren material is excluded, and by this practice every flux adds

its quota of copper while serving the purpose of producing the desired slag. In this respect the practice under the present management is an economic improvement over that of an earlier period when blast-furnace smelting was practiced and barren fluxes were purchased.

Roasting Flotation Concentrates

Roaster feed is a mixture containing smelting ore, general mill concentrate and copper-bearing iron oxide. Due to the fact that about 75 per cent of the general mill concentrate is a flotation product, 60 per cent of which is finer than 200-mesh, the general concentrate contains from 40 per cent to 45 per cent of material of that mesh and finer. The smelting ore and iron oxide are crushed to only $\frac{1}{2}$ -in., but even so, the roaster feed still contains a large percentage of very fine material. This naturally gives rise to excessive dusting in the roaster, demanding special attention to dust recovery in order to avoid a serious loss.

Roaster capacity with this feed is 110 tons per day. The sulphur content of the feed is maintained at about 20 per cent, and as long as it is 17 per cent or more there is no need of applying extraneous heat to carry on the roasting process. Oil burners are provided at the hearth doors, however, for use in case of necessity.

Typical roaster feed is composed of the following constituents by weight, and has the general analysis given in Table I:

Smelting ore	600 lb.
Specular iron ore	3,400 lb.
Mill concentrate	6,000 lb.

To this mixture, in the form of calcine, is added the following cold material to make up the reverberatory charge, the total weight being the charge per hour and six minutes, fed at thirty to thirty-five minute intervals:

Converter slag	1,500 lb.
Specular iron ore	2,500 lb.
Mill concentrate	1,500 lb.

It will be apparent that, when fettling material is included, an unusually large part of the total furnace charge is cold material, amounting roughly to 50 per cent. The conditions are quite different to those prevailing in plants where the reverberatory charge is practically all hot calcine and fluid converter slag. This accounts for the comparatively high fuel ratio, which is one barrel of crude oil per ton of total charge. The oil is preheated to a temperature of 160 deg. Fahr. and is fed to the burners under 70-lb. pressure. The furnace is equipped with two 350-hp. Stirling waste-heat boilers, but no very positive data are available from which to calculate a credit to oil consumption represented in heat recovery at the boilers. Under the conditions imposed this 19-ft. by 60-ft. reverberatory furnace has a daily capacity of 165 to 175 tons. The average grade of furnace charge and products is shown in Table I.

The new reverberatory, 19 ft. by 100 ft., is constructed with a continuous hopper across the bridge and along the side walls. Fettling will be done with a blended neutral mixture through pipes from the side hoppers instead of by hand in the old manner. Due to the character of the material to be smelted, the charge for this new furnace will be temporarily on a basis of 30 per cent calcine and 70 per cent cold charge, the latter being in even greater ratio than in the smaller furnace at the present time, although it is probable that this will be modified by providing additional roaster capacity at a later date.

Intermittent Use of Basic-Lined Converters

Converter capacity is far in excess of requirements when only the small reverberatory is in operation. This results in the intermittent use of a shell, and the prac-

tice here has thrown valuable light on the use of basic-lined converters under such conditions. The question has previously been raised as to whether converters of standard size lined with basic brick could be successfully used in comparatively small plants where intermittent operation would be necessary on account of the small output of matter. It had been feared that the converter would be subjected to such severe treatment due to the expansion and contraction of the brick lining that its use under these conditions would be unprofitable. This question was raised in the copper symposium at the International Engineering Congress in San Francisco, and at that time Mr. Laist stated that the basic-lined converter had been found to stand hard usage in intermittent service, with little cracking of the lining.

Experience at the Humboldt smelter confirms this fact, for under the method of operation no serious difficulty has been encountered. When a new lining is put in service, a number of charges are blown at short intervals to saturate and bond the brick with metal. After the lining is thus seasoned the converted will be idle for seven to eight hours between blows. On occasions a shell has been idle as long as thirty hours after a blow. According to conditions and the probable length of time the converter is likely to be down, the lining is kept warm by adding a charge of fuel, but otherwise no provision is made for the care or protection of the lining. No data are available as to production per converter lining, as the converters have not been in operation for a sufficient length of time to get any direct figures.

While magnesite brick has proved satisfactory under these conditions, Mr. E. C. King, smelter superintendent, plans to try a monolithic lining of magnesite bonded with silicate of soda or magnesium sulphate. This will be done with the idea of securing a less expensive lining, and at the same time one which may show an improvement over the use of brick.

With the new 100-ft. reverberatory in use, the smelting capacity of the plant should be increased to 450 tons per day, with a monthly production of about 1,000,000 lb. blister copper. At present the company is not equipped for blast-furnace smelting, but the erection of a blast furnace is in prospect if mining conditions in the district develop as anticipated so that a supply of suitable ore can be assured. With the ores just now available blast-furnace smelting is out of the question as a matter of economy and good metallurgy.

Our thanks are due Mr. Colvocoresses, general manager, and Mr. King, smelter superintendent, for their courtesy in favoring us with the foregoing information.

Mesothorium, a by-product from the manufacture of thorium nitrate from monazite, has properties similar to those of radium. It is considered possible that this country's resources of monazite can be used profitably in the manufacture of this valuable material. The domestic supply of monazite is found mainly in North and South Carolina, Idaho, and in the black sands of the Pacific slope.

New Regulations Governing Export Procedure.—The announcement that new United States regulations relative to export procedure will become effective Jan. 1, 1916, has created such intense interest among manufacturers and shippers that the Bureau of Foreign and Domestic Commerce, Department of Commerce, has found it necessary to reprint the new order with explanatory text. That pamphlet is just off the press and is being supplied free of charge to those interested, upon application to the above-mentioned office. All shipments for export to foreign countries or to Alaska, Hawaii and Porto Rico will be affected by the new regulations.

The Central Mill of the North Star Mines Co.

BY LEROY A. PALMER

In the Sept. 15 issue of METALLURGICAL AND CHEMICAL ENGINEERING I discussed two mills in the California gold belt, one practicing amalgamation and concentration and the other straight cyanidation. This article will deal with a mill that uses all three processes. Mills that amalgamate and then either concentrate or cyanide the tailings are common, but the process in vogue with the North Star Mines Company is unique in that following amalgamation the tailing is concentrated and the concentrate subsequently cyanided with the concentration tailing.

The North Star Mines Company operates three mills, the Champion at Nevada City and the Central and North Star at Grass Valley, Nevada County, Cal. The ore carries both gold and silver in a quartz gangue, the precious metals occurring both free and associated with pyrite, galena and sphalerite. The same process obtains at all of the mills of this company and the following on the Central mill may be taken as generally descriptive.

The ore is hoisted from the Central shaft in automatic dump skips to the bins, from which it is hauled in electric trains with side dump cars to both the North Star and Central mills, the latter being only 200 ft. distant from the head-frame. The mill, Fig. 1, which has a nominal rating of 160 tons daily, is of timber frame with corrugated iron sheathing and concrete floors, and so set on a hillside that all conveyance of ore is by gravity.

Wet Crushing

The ore is dumped into two bins, each of 200 tons capacity, fitted with 1½-in. grizzlies. The oversize of each grizzly goes to a 9-in. by 15-in. Blake crusher set to 1½ in. These crushers are run wet and discharge to that portion of the bin beneath the grizzly. A 15-hp. motor drives both crushers at a speed of 180 r.p.m. The ore is fed to them from rack and pinion gates through a steel chute fitted with vertical grizzly bars which can be dropped across it to check the flow of ore and allow waste rock to be sorted out. In this way about 5.5 per cent of the ore sent to the mill bins is rejected without going through the crushers.

Masonry Mortar Block and Steel Battery Posts

The mill has forty stamps driven as four batteries by a 100-hp. motor, but working in five-stamp mortars, Fig. 2. The stamps weigh 1050 lb. and make 107 7-in. drops per minute in order 1-5-2-4-3, with 6-in. discharge. The feed is from Challenge feeders driven

from the middle stem of each five stamps. Stamping is done through a steel screen with punched round holes 1/25 in. in diameter. At intervals of 1 in., laterally and vertically, a strip 1/16 in. wide is left unpunched for reinforcement. Such a screen gives an open area of 0.362 sq. in. per square inch of surface and has an average life of twenty days with an issue of 20 tons per day.

There are many points of interest about the batteries at the Central. First is the masonry foundation. When the mill was built in 1904 most designers clung to the old wooden battery-block. Masonry or concrete was looked upon with suspicion as it was considered that the mortar foundations must possess a certain amount of resiliency. The foundations at the Central are of granite bound with cement mortar, with concrete tops in which a rubber bedplate 1/32 in. thick is set so as to make a water-tight joint between the mortar and its foundation. The tunnel which frequently forms part of a battery foundation to permit tightening the nuts of the anchor bolts has been omitted in this construction, and the bolts are solidly embedded in the masonry. This practice has been very satisfactory as there has been no breakage of bolts or mortars and loose nuts are of rare occurrence.

Another feature is the steel battery posts at which so many millmen are inclined to look askance. Each post is made of two pairs of 8-in. channel irons bolted to the foundation and with a 4-in. spreader between the channels of each pair. This style of frame has been in continuous use since the mill commenced operation, with the failure of only four posts. When breakage has occurred it has been of a single channel iron at a time. In such a case the camshaft bearing is jacked up and the broken channel removed and replaced without stopping the battery. The advantage of this rigid construction has been well exemplified at the North Star mill of this company. With wooden battery frames the breakage of camshafts ran as high as eleven in a single year. At this latter plant cast-iron battery frames were substituted about a year ago and, as a result, the breakage reduced to four in that time, a favorable showing considering the weight of the stamps and the speed at which they are run.

The screen frame used is out of the ordinary. It is a double frame, one piece fitting inside the other and bearing against a face 1 in. wide around the inside of the outer frame. Instead of being tacked on, the screen is laid in the outer frame against a rubber gasket; the inner frame, which is of cast iron to obviate swelling, is laid against it and secured by three iron buttons. In fact, the screen is held in its frame in practically the same manner that the glass is held in a picture frame. It can readily be seen that this method

FIG. 1—CENTRAL STAMP MILL IN BACKGROUND, CYANIDE PLANT IN FOREGROUND

FIG. 2—CENTRAL MILL—BATTERIES AND PLATES SHOWING STEEL BATTERY POSTS

effects a considerable saving of time in setting up screens as compared with tacking them to their frames.

In place of the ordinary chuck-block for inside amalgamation, rifle-blocks with a height of 6 in. are used. Lengthwise of these blocks are stapled six rods of $\frac{1}{4}$ -in. square iron which act as rifles to catch and retain the amalgam. This arrangement permits of running the battery with lower discharge, and consequently faster crushing and less sliming, than with the regular chuck-block. The amalgam is easily cleaned from the rifle-blocks, most of it dropping off by simply tapping the block when it is removed from the mortar and the remainder scaling off readily with a sharp instrument such as the point of a taper file.

Stamp stems are of uniform thickness throughout instead of being tapered at the ends to fit in the boss-heads. In place of the tapering end a two-part tapered bushing of $\frac{1}{2}$ -in. steel is used. This is set in the hole in the boss-head with the straight stamp stem inside it. In case a stem breaks, instead of taking it out of the guides and turning it around, the bushing and broken part are driven out of the boss-head by means of a drift, the stem is reset in the bushing without reversing, the tappet is set up and the stamp is ready for operation.

New Design of Cam

The latest innovation is the new cam designed by Arthur B. Foote, general superintendent, which is going into use in these mills and is illustrated in Fig. 3. It was found that with the speed at which these stamps

FIG. 3—CAM FOR STAMPS

were dropped, cams and shafts were frequently broken. Aside from torsion, to which any shaft is subjected and which is greater than usual in a camshaft due to the weight lifted, a camshaft is necessarily subjected to two strains. These strains are due to the impact of the cam engaging the tappet and the jar of the stamp transmitted to the shaft through the mortar, block and battery frame. If the mortar and block are well built and the battery frame rigid, the latter strain is negligible and the most serious effect on the shaft is due to the jar of the cams picking up the tappet, which this new cam is designed to reduce to a minimum.

As is well known, the cam which has been in universal use for years past is laid out on the slightly modified involute of a circle. This new cam can best be understood by referring to the accompanying illustration. The distance from the center of the shaft to i' is equal to the major radius of the cam. From s to i' is the throw. With i' as a center and $i's$ as a radius, a quadrant is struck and divided into nine equal parts,

each subtending an angle of 10 deg. Horizontal lines drawn from these points on the arc divide the vertical radius into parts, sa' , sb' , sc' , etc., representing the sines of 10 deg., 20 deg., 30 deg., etc., respectively. A similar quadrant with a radius equal to the major radius of the cam is struck from the center of the shaft and likewise divided into 10-deg. arcs.

The curve is then laid off by striking an arc from the center of the shaft, the radius of which is equal to the distance from this center to a' until it intersects the radius a of the major arc, thus fixing the first point of the curve. Subsequent points are fixed by striking an arc from the center to b' until it intersects radius b ; from the center to c' to intersect radius c , and so on. The effect is a curve which may be likened to the spiral in a railway track, giving a radius which increases uniformly and thus imparts to the cam a uniform acceleration of speed such that when it finally disengages the tappet the velocity of the stamp is sufficient to carry it still farther upward and give it a drop greater than the actual throw of the cam.

It is claimed for this cam that it picks up the stamp with less jar than the involute design, a point that can be demonstrated by feeling the tappets of the two in operation. It requires special design for different drops as the blow on the tappet increases as the drop is shortened until at one-half the drop for which the cam is designed the shock of cam and tappet engaging would be the same as with an involute cam. Wear on the tappets is greater than with the involute design but breakage of cams and shafts, much the greater evil, is less. The designer makes no claims for it as a cure-all for battery troubles and recommends it only where there has been trouble from breakage due to high speed.

High Recovery by Amalgamation

From the batteries the pulp flows over eight amalgamation plates each 3 ft. by 20 ft., supported on frames made of angle irons, with a grade of $2\frac{1}{4}$ in. per foot. The recovery by amalgamation is about 79 per cent, an unusual amount on California ores. The rifle-blocks are cleaned every fifteen days and yield about 65 per cent of the free gold recovered. The battery plates are cleaned daily and yield most of the remainder. Traps are provided below the plates and small plates below the tube-mill, but the recovery from these sources represents only a small percentage of the total. About 100 to 130 oz. of mercury is charged daily.

On clean-up days one of the mortars is fitted with a 30-mesh screen and all sands from the clean-up and all "specimen" ore are run through this battery. The tailing from this treatment and the sand left around the dies when the battery is opened are collected in a tank and returned to the mill bin for retreatment. Sand from this clean-up is treated in a bowl, the overflow of which is settled in a concrete sump.

Concentration

After passing the traps the tailings from each of the eight plates go to a Dodd buddle, Fig. 4. This is an outward-sloping, circular-deck table, 8 ft. in diameter, with linoleum cover and annular rifles. It is driven by a head motion in which the action is transmitted through a crank with a speed of 190 r.p.m. and a throw of 1 in., so connected to the deck that the latter moves forward and back in the arc of a circle. The rifles are spaced $1\frac{1}{2}$ in. apart, and stratify the pulp, which is fed at the center, on the same principle as the quadrilateral deck tables. Beneath the deck of each table is a small spiral pump which receives the middling and discharges it through a hollow central shaft. These tables make concentrates, middlings and tail-

FIG. 4—CENTRAL MILL—DODD BUDDLES

ings. The concentrates go to a tube-mill for regrinding, the tailings are laundered to the cyanide plant and the middlings are sent by their individual pumps to the feed box of a ninth buddle, which makes the same products but retreats its own middling.

Tube-Milling of Concentrates

The concentrates from the buddles go to a 2½-in. centrifugal pump, which elevates them to a 24-in. de-watering cone. The overflow of this cone goes to the tail race and the underflow to a 5-ft. x 10-ft. tube mill which makes 14 r.p.m. The tube uses Danish pebbles and crushes so that 97 per cent of its product will pass a 200-mesh screen. Because of the nature of the feed both pebble and power consumption are low, a 20-hp. motor driving the tube mill and the nine buddles.

The tube-mill product is run over a 3-ft. x 6-ft. amalgamating plate, and thence to a 24-in. cone. The overflow of the cone goes to the cyanide plant and the underflow is returned to the tube mill by way of the centrifugal pump.

Thus the sulphides, after being separated from the gangue as concentrates, are crushed and again mixed with it, prior to cyanidation. The sole object in the concentration is to reduce the amount of fine grinding necessary in preparing the plate tailings for further treatment, and in actual practice the buddles may be said to act as classifiers for the tube mill, the classification being gravimetric instead of volumetric.

It has been found that such precious metal as can be recovered from the concentration tailing by cyaniding is amenable to this treatment without further crushing than that given in the batteries. On the other hand, the gold occurring with the sulphides is intimately associated with them and fine grinding is necessary to free it sufficiently for the solutions to act on it.

FIG. 5—OLIVER FILTERS, PACHUCA AND DECANTATION TANKS

As concentration is effected at a ratio of 40 to 1 this separation eliminates 97½ per cent of the tonnage from tube milling. The saving in power and pebble consumption is even greater than this, as the tailings are all quartz and the concentrates, the tube-mill feed, being sulphides, are much softer and more friable.

Cyanidation of Sand and Slime

The cyanide plant is situated about 500 ft. from the stamp mill at such lower elevation that the feed may be delivered at the top floor by gravity. The mingled tailings and concentrates, which classify as about 60 per cent slime and 40 per cent sand, are delivered to a 5-ft. sloughing-off cone. The underflow of this cone goes to two more 5-ft. cones, the overflow of which is divided between two 5-ft. x 6-ft. V settlers. The underflow of the second cone and the settlers goes by means of a Butters distributor to a leaching vat, of which there are six, each with a capacity of 125 tons.

Slime Treatment

The overflow of the various settlers mingles and is distributed by launders to six cone-bottom settling tanks, each 10 ft. x 12 ft. and to one Dorr thickener. The settler overflow is used as wash water on the leaching vats. A preliminary charge of lime is added at the settlers and the Dorr thickener, and the pulp drawn off at sp. gr. 1.30 to a stock tank in which sufficient lime is added to bring the strength up to 0.01 per cent; and cyanide of sodium to make the strength of the solution 0.03 per cent. This is equivalent to 0.0375 per cent, or 0.75 lb. KCN per ton of solution.

The pulp in the stock tank is agitated by compressed air and transferred by a Pohlé lift to the first of three Pachuca tanks, each 8 ft. by 15 ft., through which it is passed in series. From the last Pachuca the pulp is divided between two decantation tanks, the underflow from which goes to two Oliver filters and the overflow to the filter-solution sump. The Oliver filters make a revolution in 4 min. 20 sec., and receive a barren weak solution as a wash. The pulp is then wasted.

Details of Sand Treatment

After a leaching vat has filled and drained, the first treatment is by pumping on pregnant solution from the Oliver filter and the decantation tanks. These solutions are collected in a 450-gal. sump and raised by a 4-in. pump to the vat where they are brought up to a standard of 0.10 per cent NaCN. Thirty tons are thus pumped onto the sand and allowed to drain through. Thirty tons of strong solution, 0.10 per cent NaCN, are then run on and allowed to stand twenty-four hours. At the expiration of this time the valves are opened, and three hours after sand shows, filter solution is again run on until the sand is covered, when the vats are allowed to drain completely. The filter solution being drained, seven 15-ton charges of weak solution, under 0.06 per cent NaCN, are pumped from the sump below the Merrill presses, the vats being aerated by draining between charges until the sand appears. With the final draining of the weak solution the sand is washed for six hours before discharging with the lime water which overflows from the slime settlers.

When a vat is ready for discharging the valves, which are of Butters type, are raised, and a hose with a long nozzle thrust down beside each valve to start the sand out. When a channel is once made a Butters distributor is swung over the vat, a good head of water turned on and no further attention required except to sluice out a little sand which clings to the sides and bottom and which the distributor fails to dislodge. In this manner

a 125-ton vat can be emptied in about two hours' time with practically no personal attention.

Precipitation by Zinc Dust

The effluents of the leaching vats are titrated and sent to the pregnant strong or pregnant weak sumps, according as they are over or under 0.06 per cent NaCN. From these sumps they are pumped, after the addition of zinc dust, to one of two 10-frame, 30-in. Merrill filter presses. The precipitate is fluxed and melted without previous roasting or acid treatment.

Consumption of Chemicals and Power

The stamp mill uses about 0.75 oz. mercury per ton of ore treated. An average for a year in the cyanide plant showed consumption of chemicals per ton as follows: Sodium cyanide, 0.502 lb.; lime, 3.50 lb.; zinc dust, 0.192 lb.

Two motors are used in the cyanide plant, a 10-hp. belted to a 16 by 10-in. Rix single-stage compressor, which furnishes air at 15 lb. for the Oliver filter, Pohlé lift and Pachuca tanks, and a 20-hp. motor belted to a counter shaft, which drives all of the other machinery, including a No. 4 Roots cycloidal blower, which produces vacuum at 20 in. on the Oliver filter.

The following is a summary of all motors:

Machines	Motors	Horse-power
2 Blake crushers.....	1	15
40 Stamps.....	1	100
8 Buddies.....	1	20
1 Tube mill.....		
1 Centrifugal pump.....	1	10
1 Air compressor.....	1	10
3 Pumps.....	1	20
1 Root's blower.....		
Total.....	5	165

This indicates a consumption of 1.03 hp. per ton per day. A segregation of power costs for an average month shows cost per ton of ore as follows:

Crushing and stamping.....	\$0.126
Concentrating and tube-milling.....	.016
Cyaniding.....	.036
Total.....	\$0.178

Power is purchased from the Pacific Gas & Electric Company, which has extensive hydro-electric developments in this vicinity. The main transmission is at 40,000 volts; it is stepped down to 4000 for transmission to the mine, and there stepped down to 440 for use in the mills.

Extraction and Costs

An average value of the ore milled from the North Star mines would be very close to \$10 per ton. Extraction is at the rate of 97 per cent, leaving a tailing loss of 30 cents per ton. Costs of operation for the year 1914 were as follows:

Crushing, stamping and amalgamating.....	\$0.423
Concentrating and tube milling.....	.117
Cyaniding.....	.396
Total.....	\$0.936

Most of the mills in California, especially the smaller plants, treat their ores by amalgamation and concentration, and ship the concentrates to the smelters. This practice was followed by the North Star for some time so that some comparison of the two methods can be made. Seventy-nine per cent, or \$7.90 per ton, is recovered by amalgamation. Thirty cents is lost in the tailings, so that \$1.80 is recovered by cyanidation. This costs \$0.396 per ton plus the cost of tube milling, which will approximate 6 cents a ton. Treasure freight and mint charges amount to \$0.0075 per ton of ore treated, so that this charge on the cyanide bullion would amount to \$0.0014 per ton of ore, giving a total of \$0.46 for all charges made necessary by cessation of shipment of con-

centrates. This leaves a net profit of \$1.34 per ton from the plate tailings.

At a new mill on the Mother Lode in which a somewhat similar ore is concentrated the recovery on the vanners is 72 per cent. Applying these figures to the North Star the recovery from concentration would be \$1.51 per ton. The smelter paid for 92 per cent of the gold at the rate of \$19.50 per oz., so that the amount paid by the smelter for the concentrates from a ton of ore would be \$1.31. Freight and treatment charges amount to \$10 per ton of concentrates, or \$0.25 per ton of ore with a concentration ratio of 40 to 1. Thus the net return per ton of ore concentrated would be \$1.06, a difference in favor of cyaniding of \$0.28 per ton.

I am indebted to Mr. Arthur B. Foote, general superintendent, and Mr. Frank Provis, foreman of the Central Mill, as well as other employees of the North Star Mining Company.

San Francisco, Cal.

The Mechanical Principles of the Blast Furnace

BY J. E. JOHNSON, JR.

The opinion that the mechanical principles of the blast furnace are insignificant in number and importance has been quite generally held, and the subject has been correspondingly neglected, but in my judgment this view is founded on superficial observations, since the proper mechanical action of the furnace is the key to its successful commercial operation. There are two main requirements of mechanical action of equal importance since the fulfillment of both is vital to the process. These are: first, that the stock must settle uniformly over the whole area of the furnace and at as regular a rate as possible; second, that the gas formed by the combustion in the hearth must rise with similar uniformity of distribution and velocity so that each portion of the charge shall receive its share of the action of the gas.

In the early days of blast furnace operation there was little or no conflict between these two requirements, but with the increase in the rate of driving previously described they have become to a certain extent conflicting because of the resistance to the descent of the stock column offered by the ascending current of gas. The gas is driven through the furnace by mechanical power, and the amount of pressure which we can put upon it is in recent years virtually unlimited, so that the gas (blast) pressure has risen as fast as there was any need for it to do so; in some cases, one might almost say, faster. But the force causing the descent of the charge column is simply that of gravity, which we cannot increase except by increasing the height of the furnace, and the net result of that remedy, as I shall presently show, is to make conditions much worse instead of better.

Our first care must obviously be so to distribute the charge in the top of the furnace that the resistance of all portions of the charge column shall be the same, as already pointed out in the chapter on filling the furnace. We know but little about the theory of stock distribution further than the necessity of placing a considerable part of the fine material against the walls on account of the greater proportion of voids at the surface of the wall. Under the head of operation we shall discuss this a little more fully, but there is not enough known on the subject to be of use in this discussion, further than the above.

The Blast Pressure

Within quite recent years, and perhaps even now, there is a very considerable misapprehension on the

subject of the cause and function of the blast pressure. This is made up of three parts, the pressure required to drive the air through the tuyeres, that required to force it up through the charge column, and that to force it from the top of the furnace out through the down comer and flues. These three items make up the total blast pressure just back of the tuyeres, while to obtain the engine house pressure the pressure due the resistance of the hot blast main, the stoves, and the cold blast main must be added, the sum of which should not exceed $\frac{1}{2}$ lb. in good practice.

Many people have thought that the greater portion of the whole pressure was expended in driving the blast through the tuyeres, and that the resistance of the stock column was almost a negligible quantity, but nothing could be further from the facts. The pressure required to drive the blast through the tuyeres is in ordinary practice only about 10 per cent of the total pressure, and almost all the rest is expended in overcoming the resistance of the stock column. Finally from 1 to 3 per cent of the total is required to drive the gas through the down comer flues and burners.

In a paper published by me before the American Institute of Mining Engineers in 1905, entitled "Notes on the Physical Action of the Blast Furnace," there was given a discussion of this subject which, in the light of ten years' further experience, does not seem to require much modification, and is quoted here.

The Top Pressure

This is so simple that misconception would have seemed impossible had the attempt not been made to deduce results as to the quantity of flue-dust carried over at different furnaces from their top-pressures. The truth is that the top-pressure depends on the volume and density of the top-gases, and on the frictional resistance of the flues or mains through which they are forced, and on nothing else. The frictional resistance depends on the clear area, the length and the roughness of the mains.

Considering that the condition of the latter is generally a matter of entire uncertainty, as they vary in normal operation from perfectly clean to almost completely blocked with flue-dust and coke, calculations of the frictional resistance during operation are entirely worthless, as are also deductions as to the furnace work from the gas-pressure. If the top-pressure rises, the blowing engine automatically blows a little more pressure (never in good practice over $\frac{1}{2}$ lb.), so as to maintain the same difference between the pressure at the tuyeres and that at the top. As these variations are much smaller and much slower than those due to other causes, they are naturally never being noticed at the engine.

The Pressure Required for the Tuyeres Penetration

The pressure drop through the tuyeres has also come in for its share of misunderstanding. Within a few years the assistant to the superintendent (now superintendent) of the largest blast-furnace plant in the world contended with me strongly that the blast-pressure was nearly all expended in forcing the blast through the tuyeres, and that the pressure at the top of the bosh would not be over 2 or 3 lb. in a furnace driven with about 15 lb. He was at that time making experiments bearing on this subject, and soon found his error. This is, in fact, a matter on which we can make calculation with certainty, Fliegner, Zeuner and Weisbach having made experiments on the flow of air through orifices, and established formulæ therefor which are authoritative.

The formula for this case is

$$W = 63.6A \sqrt{\frac{P_2(P_1 - P_2)}{T_1}} \quad (1)$$

W being the weight in pounds of air passing each tuyere per minute; A , the area of the tuyere; P_1 , the absolute pressure outside the tuyere; P_2 , the absolute pressure in the furnace; and T_1 , the absolute blast temperature (= deg. Fahr. + 460).

One thousand cubic feet of air at normal pressure and 70 deg. Fahr. weigh exactly 75 lb. Since this is about an average normal condition, the conversion of volume to weight can be conveniently made on this basis (and is so made throughout this paper). Moreover, since the tuyeres are usually circular in section, we can convert the above formula to a more convenient form for immediate use, as follows:

$$P_1 - P_2 = 2.4 \left(\frac{T_1 V^2}{P_1 d^4} \right)$$

where V^2 is the volume of blast (free air) passing each tuyere per minute, measured in thousands of cubic feet, and d is the diameter of the tuyere in inches. This formula is not quite exact, being too high for low tuyere velocities and too low for high one; but it is accurate enough for the present purpose, under ordinary conditions.

For a furnace blown with 40,000 cu. ft. of blast per minute at 15.20 lb. pressure and 1000 deg. Fahr. temperature, through twelve 6-in. tuyeres, we have $P_1 - P_2$ = difference of pressure passing through the tuyeres =

$$2.4 \times \frac{1000 + 460}{15.2 \times 14.7} \times \frac{(3.3)^2}{6^4} = 1.0 \text{ lb.}$$

This is the difference in pressure required to give the necessary velocity through the tuyeres, and is, of course, fixed by the temperature, pressure, and volume of the blast, and the size of the tuyeres.

It will be seen that this pressure varies as the fourth power of the diameter of the tuyeres, so that it requires over twice the pressure to force the blast through 5-in. tuyeres under given conditions as to force it through 6-in. ones.

Other things being equal, the loss of pressure in passing the tuyeres varies as the square of the velocity, and the energy of the blast-jet also varies as the square of its velocity, hence the energy varies directly as the difference in pressure. This energy represents the ability of the blast-jet to overcome resistance in its line of action—in other words, its penetration; hence the penetration is proportional to the difference in pressure between the bustle-pipe or tuyere-stocks and the interior of the furnace. This explains the failure of many schemes of alternate small and large tuyeres, and tuyeres with flattened nozzles adapted to deliver a fan-shaped jet of air, which will cover the whole tuyere-plane equally (Gaines tuyeres). The difference of pressure, under given circumstances, within and without the tuyeres, is determined by the area of all the tuyeres, and hence the penetration in front of each of them is the same. Consequently, when alternate large and small nozzles are used, instead of the small ones throwing the air to the center and the large ones filling in the dead spaces between them, they all penetrate in figures of the same shape in the tuyere-plane; but the larger tuyeres make a larger and therefore longer one than the smaller—an effect the opposite of that intended.

Similarly the Gaines tuyeres distribute the blast so that the proper amounts are started in each direction to fill the area in that direction, but as some of these areas are much longer than others, while the difference in pressure is the same within and without the tuyeres in all directions, the penetration is either insufficient in some directions or too great in others.

For each diameter of hearth, number of tuyeres and general conditions as to blast-pressure, kind of cinder, etc., there is a given diameter of tuyeres which will throw the blast to the center sufficiently, without allowing great dead spaces on the walls between the tuyeres. If the tuyeres be made smaller than this, the force of the air-jet straight ahead will take an excess of blast to the center of the furnace and allow pilasters, so to speak, of dead material to form on the walls between the tuyeres, so reducing the active area of the hearth and making the furnace work too hot at the center. If, on the other hand, the size of the tuyeres be increased, the blast-jets fail to reach the center, but spread out laterally to such an extent that they may even cut the walls between the tuyeres, while a cone of dead material forms in the center.

One of the best furnace-men in the country once told me that he had banked his furnace, cut through the jacket, and put in additional tuyeres; that in cutting in for these they had found something like 3 ft. of perfectly dead material on the walls, and that after starting up they had made nearly 50 per cent more iron than the best they could do before. Naturally, he was a believer in multiple tuyeres, though not extreme in his views.

On the other hand many illustrations could be gathered in which the results were slight or even objectionable, under circumstances at first sight not very different.

The explanation is not difficult. In the first case the size of the tuyeres had probably been increased until they were as large as the blow-stocks and bustle-pipe connections could supply, and the velocity of the blast into the furnace could not be reduced by further increase in size of the tuyeres, although it was very much too high, with the blast all going up the center, and very heavy pilasters built up between the tuyeres on the bosh-walls, as shown by the depth of dead material cut through, before fire was reached.

When the increased number of tuyeres was put to work the velocity of the air-jets was diminished, and they were able to spread out laterally so as to melt off the pilasters, and increase the effective area of the hearth very materially. But if the bustle-pipe connections and tuyeres had been enlarged so that the proper quantity of air at the required temperature and pressure could have gone through them at the proper velocity, the results would have been in all probability almost if not quite as good as those attained by the use of a greater number of tuyeres.

If now, thinking to profit by this example, some furnace-man whose furnace was already equipped with a proper size of tuyeres, had followed a similar course, he would have so far reduced the velocity of the blast-jets that their penetration would have been insufficient; and they would have spread out sidewise, scouring the walls between the tuyeres and allowing a cone of cold material to form on the bottom in the center. In such a case, unless the area of the individual tuyeres had been reduced in proportion as their number was increased, the condemnation of multiple tuyeres would have been as hearty as its praise was in the first case.

It is not to be overlooked, however, that, other things being equal, the area of the pilasters on the walls varies nearly as the square of the distance between consecutive tuyeres or inversely as the square of the number of tuyeres. On the other hand, it must be remembered that the saving in hearth-area obtained by increasing the number of tuyeres increases much more slowly with each increase in their number, and that the difficulty and expense of maintenance of the tuyeres increases with each increase in their number. It is therefore not strange

that the best opinion tends more and more strongly to a moderate number of tuyeres.

Before leaving this subject, I wish to call attention to a simple means of determining the activity of the different portions of the tuyere-plane, which is, of course, a direct measure of the penetration, and therefore of the correctness of the nozzle area. This method consists in passing a $\frac{3}{4}$ -in. or $\frac{7}{8}$ -in. rod through one tuyere, and pushing it through the column of stock as quickly as possible, until it strikes the far side of the hearth, leaving it from twenty to fifty seconds, and quickly withdrawing it. The relative temperatures it has reached at different points will be a correct measure of the activity of the hearth at the corresponding points.

I am indebted to Mr. Austin Farrel of the Cleveland Cliffs Iron Company for this simple but effective expedient. When he told me of it three years ago, I believe it was very little known, though it has since come into use to some extent, but is probably still unknown to some who will be as glad to hear of it as I was.¹ The results shown by this test are sometimes surprising. I have seen a rod which had been put into a furnace, blown with about 11,000 cu. ft. of wind through six 6-in. tuyeres, come out almost dead black for 5 ft. in the center, and so nearly burnt in two at the noses of the tuyeres that it broke at those points when it hit the ground. (The tuyeres were 8 ft. from nose to nose.)

On the other hand, a reduction of the size of the tuyeres to 4 in., while it showed much better results on the rod and lowered the bottom of the furnace (which was high before), was succeeded after a few weeks by a considerably greater loss of tuyeres and coolers. This is believed to have been caused by the tops of the pilasters which formed on the bosh walls, making gutters, which led all the dripping iron and cinder down on top of the tuyeres and caused their more speedy destruction. The pilasters, of course, were formed by reason of the too great velocity and penetration of the blast jets, as before explained.

It seems very probable, therefore, that where furnaces have a small number of tuyeres, it is, on account of this secondary effect, unsafe to increase the penetration so much as to bring the test rod to a uniform temperature clear across the hearth. In furnaces with more tuyeres, the pilasters, in consequence of their smaller cross-section, do not extend so far up on the bosh walls, consequently this danger is much less serious. This is a point in favor of a larger number of tuyeres than six; but the necessity for this is now everywhere admitted, if large product be aimed at.

During the interval since this was written practice in regard to tuyeres has now settled down to a very moderate number of tuyeres for hearths even larger than were dreamed of at that time. Mr. H. A. Brassert has recently stated in a paper before the American Iron and Steel Institute, May, 1914, that furnaces with hearths as large as $16\frac{1}{2}$ ft. or 17 ft. in diameter gave as good results with ten tuyeres as with fifteen, a statement which, in view of his experience, is authoritative.

The formula for the drop in pressure quoted above has been quite extensively used by some furnacemen to obtain comparative figures for penetration under different conditions. Mr. E. B. Cook of Cleveland in particular has made a careful study of this matter and has been good enough to communicate the results to me. He has found that the pressure-drop for small hearths ranges in good practice from 0.5 lb. to 0.75 lb., and on large furnaces from 0.8 lb. to 1.2 lb., except on the furnaces with very large hearths above mentioned, in which the

¹Since writing the above, I have been informed by Mr. Frank Firmstone that this expedient has been described by French and German writers—in some cases, several decades ago.

figure is about 2 lb., a fact to which we shall refer later.

What is meant by penetration is not always easy to grasp at first sight. We think of the furnace as being filled with gas rather than as containing a violent current of gas, particularly in the hearth where the blast comes in horizontally and must quickly take a vertical direction. In order to make the state of things plainer we can conceive of a tube of glass, 6 in. in diameter, filled with broken coke, with say six jets of water coming into it near the top and flowing down through the coke under the influence of gravity.

Assume that the quantity of water per minute remains constant under all conditions and that first the nozzles of the jets are quite large so that the water flows into the tube with a very low velocity. We shall obviously have a condition such as I have tried to portray in Fig. 1, the current of water running principally down the sides of the tube and only reaching the center after it has travelled down a long way.

Imagine now that while the quantity of water remains the same, the jets are very much reduced in size so that their velocity is very great under the influence of a high pressure. We shall obviously have the condition shown in Fig. 2 in which the water is driven, in spite of the resistance of the coke, very largely to the center where the jets are stopped by impact upon one another. Here we shall have the greater portion of the water flowing down the center, and the sides not receiving their proportion for quite a distance down the tube.

Obviously now we can establish an intermediate condition in which the velocity of the jets is considerable but not excessive, as shown in Fig. 3. They are given sufficient energy so that by the time they reach the center the energy is all exhausted by the resistance of the broken coke, and there is no surplus to pile up the water in the center and cause a disproportionate flow in that portion of the tube. At the same time the velocity is sufficient to permit only that quantity of the water to flow down the space next the walls which is proportionate to the area of that region. These are precisely similar to the conditions of deficient, excessive and correct penetration in blast-furnace practice.

The penetration test in the quotation above given, in which the rod was absolutely black all over except for a couple of feet near the ends where it was white hot was made on a furnace with tuyeres very large in relation to their number and to the amount of blast blown; this furnace formed a huge "onion" of solid iron on the hearth which remained throughout the blast. The molten iron lay in the annular space between the onion and the crucible walls, and on account of the small area

of this space stood at a considerable height therein at cast time; when the furnace was cast the iron flowed with the greatest violence for one or two minutes and was then followed by the cinder, the cast being over. When the furnace was blown out this huge onion was found welded fast to the salamander, and rising some 2 ft. or more above the bottom of the hearth. There can be no possible doubt that this furnace worked continually with a cold center—a center column of stock which was not traversed by the gas, and which was only eaten away by a slow process of solution in the iron and cinder and stood like a cold poultice on the hearth. In subsequent blasts smaller tuyeres were used and the same conditions never arose again.

The operation of testing the penetration with an iron rod, described above as generally carried on, is rather unsatisfactory because no matter how excessive the supply of blast in the center may be it is obvious that there is no deficiency of blast supply near the walls in the space immediately in front of the tuyeres which the rod must traverse when the test is made through the tuy-

FIGS. 4 AND 5—LOCATION OF TEST ROD HOLES IN PENETRATION TESTS

FIGS. 1, 2 AND 3—CONSTANT QUANTITY OF WATER DISCHARGED THROUGH NOZZLES OF DIFFERENT SIZE INTO TUBES FILLED WITH BROKEN MATERIAL, ILLUSTRATING THE VARIATIONS IN BLAST PENETRATION

eres, the condition being somewhat as roughly indicated in Figs. 4 and 5, showing the condition in the tuyere zone of a furnace having six tuyeres with deficient and excessive penetration, respectively. Obviously the lines on which we should test are AB and not CD. This we can easily do, if there are cooling plates between the tuyeres and approximately on the level of the tuyere centers as there should be, by fitting the cooling plates half way between the tuyeres with a copper pipe, passing from the butt of the plate through into its nose, carefully screwed into the latter surface and pined over, the butt end of the cooling plate being caulked up against the copper pipe to make a tight joint.

This would give a water-cooled opening of sufficient size to admit a test rod and a penetration test made here would quickly show excessive penetration. These holes, of course, would be plugged with clay or could be closed with a screw plug, when not in use.

I have never tried this method of testing myself, but I see no reason to anticipate that it would not be per-

fectly successful, and it should certainly give much more accurate information than testing through the tuyeres.

The Blast Pressure Required to Overcome the Resistance of the Charge Column

This is obviously a subject not open to accurate mathematical investigation of the kind that Fleigner was good enough to make in order to supply the means for determining the pressure drop through the tuyeres. We can never hope for such a solution since from the nature of the case the conditions are not only of infinite variety but change from instant to instant, and the pressure required to blow a given furnace is something in which no rule has ever been suggested for even approximate guidance. Nevertheless this also follows a natural law, and in spite of the variation in the conditions is amenable to mathematical expression, the constant, of course, being derived entirely from practice.

Let us consider first the relative velocities of the gas column at different zones of the furnace as affected by its volume and by the area of the furnace at the corresponding zone. The three zones at which we have any knowledge are the tuyeres plane: the top of the bosh, where we assume that combustion to CO is complete and that the gas has given up heat generated by its combustion down to the critical temperature; and the stock line of the furnace. The volume of the gas is determined by three circumstances, its chemical condition, its absolute temperature, and its absolute pressure.

Let us assume that the tuyere pressure is 15.3 lb. or 30 lb. absolute, that the top pressure is 0.3 lb. or 15 lb. absolute, and that the pressure at the top of the bosh has dropped in the same proportion as the fraction of the total height traversed, let us say one-fifth to 12 lb. or 27 lb. absolute. Let us assume further that the blast temperature is 1200 deg. Fahr., and the top temperature 400 deg. Fahr., the critical temperature prevailing at the top of the bosh, as before stated, being 2750 deg. the absolute temperatures corresponding to these are 1660 deg., 860 deg. and 3210 deg. Let us further assume in accordance with average practice that the top gas contains 60 per cent nitrogen.

At the tuyere plane the blast obviously enters as air; at the top of the bosh the oxygen of the air has become CO which increases the gas volume, as compared with air, from 1 to 1.207. At the stock line the nitrogen which is the same in absolute amount has fallen from 79.3 per cent to 60 per cent, so that the total volume must have increased by chemical action, additions, etc., to 1.32. Multiplying together the results of these three conditions we find that the relative volume at the tuyeres is $1 \times 1660/30 = 55.4$; the volume at the top of the bosh is $1.207 \times 3210/27 = 143$, and the volume at the stock line is $1.32 \times 860/15 = 75.5$.

If the gas is to travel at a uniform velocity the area at these levels must be proportional to its absolute volume at these points, and in a circular column the diameter of the column must be proportional to the square root of these volumes. These square roots are: 7.46, 11.95 and 8.67. Multiplying all of these by a constant factor to bring them to recognizable dimensions they become 16.1, 25.6 and 18.6. These are not very far from the diameters at the tuyeres, the bosh and the stock line of a 90-ft. furnace though the bosh diameter is too large and the hearth a little small.

We see, therefore, that if the furnace were empty the gas column would pass through it at an approximately constant velocity from top to bottom; the same would also be true if the percentage of voids if all portions of the furnace was the same. It is impossible for us to assert that this is true but I am unable to perceive any reason why we should not expect that it is approx-

imately true since the variation around the top of the bosh is explained by changes in other conditions, as we shall presently see.

A heterogeneous mixture of materials of different sizes must, by mixing, reach a sort of irreducible minimum of voids depending on the size and kind of the materials. From the top of the bosh down to the tuyeres the coke is burned, and as the process is necessarily progressive the average sizes of the pieces at the tuyere zone must be much smaller than those at the top of the bosh which in a general way leads us to expect a proportional decrease of the voids, which would naturally necessitate a diameter of hearth larger than the gas volume alone would account for.

The materials other than coke which have existed as solids down to the top of the bosh are liquified as they pass below that zone with a considerable diminution of volume, and a much great diminution of their resistance to the passage of the blast on account of the closeness of their contact with the coke when in the liquid form, hence the available volume of voids is greater than in any other zone of the furnace either above or below and the area may be proportionally smaller than the gas column estimate would lead us to expect.

Considering these various conditions we may tentatively assume that the velocity of the gas column upward through the furnace is constant, though this is not necessary to the correctness of the formula for blast pressure, presently to be developed.

Turning now to the matter of the resistance to the passage of the gas offered by the stock column it will perhaps be as easy to approach it by the path I first followed as by any other.

A number of years ago there was an active controversy in one of the technical journals concerning formulas for the flow of compressed air in pipes. Numerous formulas were proposed and the results obtained by applying them to the same problem were truly startling. It finally reached the point where one correspondent declared that the initial pressure for a given flow in a long pipe line could be dropped from 160-lb. to 100-lb. gage pressure by the simple expedient of raising the terminal pressure of the air leaving the pipe line from atmospheric to 40-lb. pressure.

At this point I began to wonder if there might not be something wrong with the formula which all the parties were using in one shape or another, and with one set of constants or another. This formula was merely the mathematical expression of the statement that the friction of a fluid through a conduit is proportional to the length of the conduit, to the square of the velocity, to the wetted perimeter of the conduit, divided by its area, and to a coefficient depending on the liquid. This is a fundamental law and is absolutely correct, but a little consideration showed that when the air in the above example dropped from 180-lb. pressure absolute to 15 lb. absolute, its volume and therefore its velocity increased twelve times, and as the friction is by the law proportional to the square of the velocity the friction in this part of the pipe would obviously be 144 times as great per unit of length of pipe as in the high-pressure portion, except for the effect of the density.

To see what effect this consideration would have on the results I took one of the examples quoted and divided the length of pipe given into ten sections, figured the drop of the first section, then with the new velocity consequent on the increased volume due to the decreased pressure calculated the pressure drop for the second section, and so on, finally reaching a reasonable result. It presently became obvious that this was a legitimate field for a little calculus.

It is admitted that the friction of gases is proportional to their density, as it obviously should be, other things being the same, so we must introduce this factor into the fundamental law which may be expressed as a formula by putting

P_1 = the initial pressure absolute.

P_2 = the final pressure absolute.

L = length of the pipe.

D = the diameter of the pipe.

W = weight of air passing per minute.

S = density of air.

V = volume of free air per minute.

v = velocity in pipe per minute.

$$(\pi D) \left/ \left(\frac{\pi}{4} D^2 \right) \right. = 4/D = \text{wetted perimeter} \div \text{area.}$$

K is a constant to be determined by experiments; all constant factors are thrown into this and may be disregarded until the final equation is reached, proportionalities being treated as equations.

Then

$$V = W/S$$

and

$$v = V \left/ \left(\frac{\pi}{4} D^2 \right) \right. = W \left/ \left(\frac{\pi}{4} D^2 S \right) \right.$$

Then the fundamental law for a short section of pipe becomes

$$P_1 - P_2 = \frac{4kLSv^2}{D} = \frac{4kLS}{D} \times \frac{W^2}{(\pi/4)^2 D^2 S^2} = \frac{64kLW^2}{\pi SD^5}$$

but S is proportional to P and we can put

$$P_1 - P_2 = \frac{64kLW^2}{\pi D^5 \times (P_1 + P_2)/2}$$

For the very short length of pipe dL we have

$$P_1 - P_2 = dP \text{ and } (P_1 + P_2)/2 = P$$

so that we have

$$dP = \frac{64kW^2}{\pi D^5 P} dL \text{ or } PdP = \frac{64kW^2}{\pi D^5} dL$$

whence

$$P_1^2 - P_2^2 = K \frac{W^2 L}{D^5}$$

By applying the results of the extensive experiments on the flow of compressed air in pipes at the Mont Cenis tunnel I derived the necessary constant and the formula took the final form of

$$P_1^2 - P_2^2 = 0.0006 \frac{W^2 L}{D^5}$$

in which form it has been very widely used, and extensive experiments made in the natural gas lines have completely verified its correctness when the proper factor for the density of natural gas is used.*

I had made a number of attempts to understand the relations of changes in blast volume to changes in pressure on a given furnace, and also the relation between the pressure required for a given volume of blast on two furnaces of different sizes, but I had never been able to obtain any results at all in accordance with the facts. Gradually it began to seem that the same laws might be applied in this case as in the case of the friction in pipes. That is to say, it was a case of gaseous friction with all the consequence of changes in velocity due to changes in pressure, but with this important difference that the friction in case of the round conduit comes only from the perimeter of the pipe, whereas in a furnace shaft filled uniformly with solid material the ratio of surface to volume of interstices is the same over

the entire area, and therefore the factor for wetted perimeter is not needed.

Let us consider two furnaces of the same relative proportion, one, A, 50 ft. high by $12\frac{1}{2}$ ft. bosh diameter, of 4000 cu. ft. capacity and blown with 8000 cu. ft. of wind per minute. This would require, we know by experience, about $3\frac{1}{2}$ lb. pressure. The other, B, 100 ft. high by 25 ft. bosh diameter, of 32,000 cu. ft. capacity and blown with 64,000 cu. ft. of wind, what pressure will be required for it?

Let us assume that the two furnaces are each divided into fifty equal zones, those of A being similar to those of B, though only half as high. It is obviously reasonable to assume that the specific resistance of the stock to the passage of the gas will be the same in the corresponding zones; that is, that the ratio of interstices to surface of stock exposed will be the same in corresponding zones in each. Let us assume for the present that the shape of the furnaces is such that the velocity of the gas through them is constant in all zones, or if not, that it varies similarly in the two stacks so that this variation can be eliminated from consideration. This reduces the fluid friction of the gas current down to the same basis as that for flow in a uniform conduit.

Then proceeding as in the previous case we put

D = furnace diameter.

H = furnace height.

P_1 = absolute pressure at the tuyere zone.

P_2 = absolute pressure at the stock line.

W is the wind blown per minute measured under atmospheric conditions.

S = density of the air (proportion to the pressure when the temperature is the same).

W = velocity of gas through the furnace proportional

$$\text{to } \frac{W}{SD^2}$$

Proceeding as before we find for a short section dH that

$$dP = K \frac{W^2 S}{SD^5} \times dH = K \times \frac{W^2}{SD^5} \times dH$$

If we substitute P for S , to which it is proportional, we have

$$PdP = K \frac{W^2}{D^5} \times dH$$

and by integration

$$P_1^2 - P_2^2 = K \frac{W^2}{D^5} H$$

The constant K we determine from the pressure assumed from general experience in the case of the small furnace, and with this value of K we determine the pressure in the large furnace to be 19.4 pounds as follows:

For our small furnace, $P_1 = 18.5$, $P_2 = 15$, $W = 8000$, $H = 50$, and $D = 12\frac{1}{2}$, from which we can find K as follows:

$$(342 - 225) = K \frac{64,000,000 \times 50}{24,400} \text{ or } K = 0.00089$$

and for the large furnace using the same value of K we get

$$P_1^2 - 225 = 0.00089 \times \frac{64,000^2 \times 100}{390,625} = 1,050,000 \times 0.00089 = 935$$

$$P_1^2 = 225 + 935 = 1160, P_1 = 34.1 \text{ absolute} = 19.4 \text{ gage.}$$

It must be thoroughly understood that the value of K is derived entirely from experience. There is no known method by which we can even attempt to determine its value mathematically. We must therefore determine a value for it which will fit established practice reasonably well before we can safely use the formula or com-

*I subsequently found that this formula had been developed at least once and probably several times before, but apparently the earlier investigators did not take the trouble to determine the constant, without which the formula is practically valueless, and it had never come into general use.

FIG. 6—BLAST-PRESSURE CHART

Instructions for Use of Blast Pressure Chart.—Note first of all that there are two rows of figures along the bottom giving bosh diameters, and two rows along the left-hand end giving blast volumes. The inside rows of these must always be used together, or the outside rows; never figure from the inside in one row and from the outside in the other row. Some of the figures are duplicated in the inside and outside rows. This is to extend the scale and flexibility of the chart. As long as the corresponding rows are used together it makes no difference which one is taken.

Take the vertical through the figure at the bottom giving the bosh diameter and the horizontal through the figure at the left giving the blast volume in cubic feet of piston displacement. From the intersection of these draw a diagonal through the origin and extend it until it cuts the vertical through the height of the furnace given just inside the cross-sectioned area of the diagram at the top. From this intersection draw a horizontal to the curve, and from the point of intersection draw a vertical to the top of the diagram and read the pressure in the figures along the top edge of the cross-sectioned area. For instance, find the normal working pressure of a furnace, 22 ft. bosh diameter by 90 ft. high, blown with 45,000 cu. ft. of wind piston displacement per minute. The vertical through 22 in the outside row intersects the horizontal through 45,000 in the outside row at the point A. Through this draw a diagonal toward the origin until it cuts the vertical through 90 ft. furnace height at B. From this draw a horizontal to its intersection with the curve at C, and from this draw a vertical to the point D at the top of the diagram, which shows a little less than 13 lb. pressure.

pare the pressure of different furnaces with its aid. By comparisons with actual results I reached the conclusion that the proper value of K was 0.00070, and in order to make the formula easy of application I prepared a diagram, shown at Fig. 6, with the aid of which, with the accompanying explanation for its use, problems involving furnace pressure may be solved in one minute.

Through the kindness of a number of furnacemen this formula has been checked against practice on a number of furnaces, with the result that I believe its indications are about a pound too low in the region of 15 lb. pressure, and it is probable that the value of K should be 0.0008. While there are variations, the correspondence between the results of this formula and the pressures actually found at furnaces of different sizes and operating under different conditions is very much closer than might be expected, so that I believe it may be safely assumed to be founded on correct hypotheses, and in the absence of knowledge based on practice to give a reasonably reliable indication of the actual pressure that may be expected under any given conditions.

It will be noted that this pressure includes both the stock column resistance and the tuyere pressure. It would be possible to subdivide it so as to give stock column resistance only, but this is not worth while for

two reasons: First, the variations of tuyere pressure drop are smaller than the normal variation in blast pressure. Second, the tuyere pressure drop increases with the size of the furnace, as stated above, so that its variation is roughly the same as that of the stock column pressure. It is therefore not worth while to differentiate them, but is simpler and is exact enough for all practical purposes to include both in the one formula.

The top pressure assumed for the chart is that of the normal atmosphere, 14.7 lb., on the basis that most of the furnaces in the country are located several hundred feet above tide level, and the actual atmospheric pressure is about enough lower than that at sea level to allow for the top pressure required to drive gas through the flues.

It should be noted that variations from this formula tend to be, to a certain extent, self-compensating. That is to say, if owing to any condition the pressure rises, this in turn increases the density, which reduces the velocity and thereby tends to keep down the pressure drop. This may be illustrated by the electrical resistance of the tungsten lamp as compared with the carbon. The resistance of carbon decreases with temperature, therefore a slight rise in voltage, driving more current

through the filament, heats it hotter, reduces its resistance and tends to let still more current pass, whereas with the tungsten lamp the resistance increases with temperature, so that an increase in voltage results in an increase in temperature, and this in turn in an increase in resistance, thereby tending to cut down the increased flow of current and reduce the variation due to its effect. As a result tungsten lamps show much smaller variations of luminosity with a given variation in voltage than do carbon lamps under the same conditions. So owing to the nature of gaseous friction variations in blast pressure are much smaller than they might be expected to be.

This fact probably has something to do with the comparative correctness of the blast-pressure chart over wide variations in conditions.

It should be clearly understood that the pressure given by this formula is only the normal working pressure. The furnace may get into a condition in which the gas blows through easily, due, perhaps, to a scaffold on one side above and another on the opposite side below, or something of that kind, and in such comparatively rare cases the actual pressure will be lower than that shown by the chart.

On the other hand, very many causes may make the furnace work with a considerably higher pressure than that given by the formula; there is, in fact, no limit in this direction except the power of the engines. First, the furnace may form a ring scaffold which forces all the gas to go through a sort of nozzle much smaller than the diameter of the furnace, and consequently with a much increased velocity and resistance. Second, the slag may become tough and stringy, and therefore be blown by the blast into the interstices of the coke, greatly obstructing them instead of running in quiet trickles down over the surface. Third, the hearth and bosh in case of serious trouble may become almost frozen solid, with the result that only very small passageways are left through which the blast can find its way, and the slag in those is excessively tough and stringy. Fourth, and probably most common of all, the deposition of carbon (described in the article on chemical principles), which is sometimes extremely voluminous, in cases amounting to several times the bulk of the ore, may be deposited in the interstices of the stock in such quantity as to greatly obstruct the flow of the gas. These are all conditions which we have difficulty in proving; to measure them quantitatively is, of course, inconceivable. We cannot therefore hope to fit a formula to these diverse variations.

Leaving abnormal conditions to one side it has been found at a number of plants that the formula coincides with the results of normal-working furnaces with a degree of accuracy which is fairly satisfactory in so approximate a matter, though, as before stated, it is perhaps a little low. It should be stated that the quantity of air given on the chart is that measured by piston displacement in normal practice. This is indefinite to a certain degree, but unfortunately we have nothing else, and with the great improvements of blowing engines which have occurred in recent years this is sufficiently accurate for our purpose. It is probable that the actual air corresponding is less by about 12 per cent under the ordinary conditions of good practice.

It will be noted that this formula takes no account of difference in the condition of the ore, which varies from the fine sand of the Mesabi to the all-lump ore of Southern practice. There is probably a slight variation due to this cause, but owing to the self-compensating nature of the action described above, it is very much less important than might be expected, or at least the formula fits furnaces under Southern conditions

about as well as it does those running on Lake ore, which means generally from 50 to 90 per cent Mesabi.

It is greatly to be hoped that all interested will apply this formula to their conditions, and if they will communicate the results of such application to the editor of this journal, with as full a description as possible of the conditions, it will promote the collection of data which will either put this formula on a firm foundation or upset it altogether. It is presented here because of the absolute lack of any other means of reaching the desired end, and because the results of its application were found to coincide so much more broadly with practice than was expected when the formula was developed.

The Effects of Blast Pressure

The pressure of the blast tends to retard and make more difficult the descent of the stock. It is curious that this idea is not more generally held (a few years ago it was almost entirely ignored), but on the basis of Newton's first law of motion, that "action and reaction are always equal and in opposite directions," it seems impossible to escape the conclusion that if the stock column resists the ascent of the blast at the rate of so many pounds per square inch, then necessarily the ascent of the blast resists the descent of the stock by an equal number of pounds per square inch.

This view has not always been admitted from the theoretical side, but practically it has been recognized by the century-old practice of slacking the blast when the charge column was "hung" and refused to settle properly.

From this consideration it is very evident that to secure free and regular settling of the charge one of the prime conditions is to have the blast pressure low in relation to the weight of the charge column, and this, with the great expense involved in compressing the blast to a higher pressure than is absolutely necessary, would lead us to believe that high pressure was an unmitigated evil, and that in general the lower the pressure with which a furnace will work, the more satisfactory its work will be. But while this is a fundamental consideration, and should be the controlling one, there is another condition brought about by high pressure which is worthy of careful consideration, as first pointed out to me by George G. Crawford. This consideration is that the velocity of combustion is greatly augmented by pressure, and as most modern furnaces are driven to the limit set by their ability to burn the carbon in the space available for that operation this is a consideration not lightly to be neglected. Moreover, quick combustion means a decided localization of the zone of highest temperature, which in turn means lowering the zone of fusion and bringing more closely under control that region of the furnace at which scaffolding due to pastiness is likely to arise.

The standardization of bomb calorimeters is the title of Circular No. 11, issued by the Bureau of Standards. The paper describes briefly the methods of calibrating and using bomb calorimeters. Provision is made by the Bureau for distributing standard samples of pure materials, such as sugar, naphthalene and benzoic acid, for the purpose of standardizing calorimeters and securing uniformity in heat tests.

The Haynes Stellite Company of Kokomo, Ind., has placed a contract with the Snyder Electric Furnace Company, Chicago, for a 1½-ton per 24-hr. electric melting furnace which has a one-eighth-ton holding capacity, 50 kw. input and will produce 12 heats per 24 hr. The Haynes Stellite Company is the manufacturer of the cutting alloy "stellite."

The Safe Transportation of Explosives and Other Dangerous Articles*

BY COL. JAMES L. TAYLOR

Before the organization of the Bureau of Explosives, as it is commonly called, this important matter was regulated through the local regulations of the railways, and, as might have been expected, such regulation was often found to fail of its purpose in the particulars of that standardization and uniformity so indispensable to the enforcement of regulations which instituted or attempted to institute departures from the prevailing methods of competition and of practices that had previously been permitted to exist. The consequences of these conditions were in too many instances disastrous, and the progress toward their amelioration was of a very slow and disappointing character until the organization of the Bureau of Explosives was effected and its regulations put into force by practically all of the railways embraced in the organization of the American Railway Association.

Following this condition as a natural sequence, it was finally adjudged necessary to have the matter placed in the category of federal control, and by appropriate legislation to make the enforcement of the regulations one of universal and standard requirement. And so on May 30, 1908, the President of the United States approved an act of Congress under the title, "An act to promote the safe transportation of explosives and other dangerous articles and to provide penalties for its violation." The Interstate Commerce Commission was made that branch of the government to whom was entrusted the fixing and promulgation of the regulations to make the act effective within ninety days after its passage. Well within the limit of that period the regulations were duly promulgated, which in the language of the act were to be "the best known practicable regulation" for the purposes of the act, and which, in fact, were in a large degree the regulations of the American Railway Association, with some modifications which time and experience had demonstrated as necessary. They were issued in the name of and by the authority of the commission as the regulations to govern the transportation of the articles referred to.

On March 4, 1909, the foregoing act of Congress was repealed and the date of such repeal was to be on Jan. 1, 1910, and the title of the repealing act is a very suggestive one, for it is entitled "An act to codify, revise and amend the penal laws of the United States, to take effect and to be in force on and after Jan. 1, 1910." From that date to the present the legislative regulation of this matter has been one of federal law. The sections of this act last named, which apply more especially to the subject of our consideration at this time, are included in Sections 232 to 236 inclusive. As the first three are practically the first act in its essence, I will not repeat them. Sections 235 and 236, however, I will repeat, as they stand upon the record of the law books to-day, and have stood there since Jan. 1, 1910:

Section 235. Every package containing explosives or other dangerous articles when presented to a common carrier for shipment shall have plainly marked on the outside thereof the contents thereof; and it shall be unlawful for any person to deliver, or cause to be delivered, to any common carrier engaged in interstate or foreign commerce by land or water, for interstate or foreign transportation, or to carry upon any vessel or vehicle engaged in interstate or foreign transportation, any explosive, or other dangerous article, under any false or deceptive marking, description, invoice, shipping order, or other declaration, or with-

out informing the agent of such carrier of the true character thereof, at or before the time such delivery or carriage is made. Whoever shall knowingly violate, or cause to be violated, any provision of this section, or of the three sections last preceding, or any regulations made by the Interstate Commerce Commission in pursuance thereof, shall be fined not more than \$2,000, or imprisoned not more than eighteen months, or both.

Section 236. When the death or bodily injury of any person is caused by the explosion of any article named in the four sections last preceding, while the same is being placed upon any vessel or vehicle to be transported in violation thereof, or while the same is being so transported, or while the same is being removed from such vessel or vehicle, the person knowingly placing, or aiding or permitting the placing, of such articles upon any such vessels or vehicle, to be so transported, shall be imprisoned not more than ten years.

These are the requirements of the law which must be complied with, and a full understanding of the law is requisite which must be had by every person in any way brought into connection with the transportation of these dangerous articles.

The "other dangerous articles" (besides explosives) are chiefly inflammable gases, inflammable solids or oxidizing materials, acids or corrosive liquids, compressed non-inflammable gases, etc.

Probably the most important feature is the safeguarding of these dangerous articles by the security of their packing. And I am happy to state that in this respect the Bureau for the Safe Transportation of Explosives and Other Dangerous Articles has achieved a notable success in securing, after a somewhat prolonged effort, the full support of the manufacturers and shippers of acids, charcoal, friction matches, compressed gases and other articles of chemical industry, most of whom have co-operated with us by giving us the full benefit of their experience, especially in the matter of formulating suitable rules for transportation.

In a similar way, too, we have secured in a very large degree the co-operation of the manufacturers of shipping containers for these classes of dangerous articles, especially in railway transportation.

It is well known that there is no well-defined limit to the forces that may act upon the shipping containers which include the crushing weight of other packages piled upon them; the shifting of freight in the cars incident to transportation conditions; the failure of many types of boxes of various kinds to carry the load of other packages; the proper resistance to the shocks incident to the handling of cars, and the proper methods to resist the force of such shocks, by a proper cushioning of containers to resist them, as well as the high pressures slowly applied.

In this connection I would refer to a series of monographs upon this subject: The lectures of Col. B. W. Dunn, late of the Ordnance Department of the United States Army, who is the chief inspector of the Bureau of Explosives of the American Railway Association, delivered upon many occasions, among which were the lectures at the twenty-fifth semi-annual convention of the National Association of Box Manufacturers, at Detroit, Aug. 28-30, 1912; the address at the first annual convention of Manufacturers of Corrugated Fiber Containers, held in Atlantic City, July 7-9, 1914, and finally, and perhaps the most important of all in the profitable character of the information which it gave, the address of Colonel Dunn which appears in the Proceedings of the New York Railroad Club at its meeting April 15, 1910, under the title "Stresses Developed by Collisions of Freight Cars."

Abrasive Materials.—The production of abrasive materials in 1914 is given in Bulletin II:29 of the Geological Survey.

*Synopsis of a lecture delivered before the First National Exposition of Chemical Industries, New York City, on Sept. 23, 1915. The author is assistant to the chief inspector of the Bureau of Explosives of the American Railway Association. The address was illustrated by numerous stereopticon views.

The Barium Industry in the United States Since the European War*

BY MAXIMILIAN TOCH

Within the last eighteen years there have been three attempts to establish a barium industry in the United States prior to Aug. 1, 1914, and all three of them have been unfortunate failures. I have investigated the cause of these failures and I find that two of them failed through financial and chemical mismanagement, while the third was utterly destroyed on account of its inability to compete against foreign competition.

I have been identified with the manufacture of barium products for nineteen years, and while the venture of my firm has been successful it was never very large and was confined to one particular barium salt, which sold entirely on account of its quality.

A well-known and successful chemical corporation manufactured barium chloride and barium sulphate in New York City a little over fifteen years and made very good products. As soon as they turned out reasonable quantities some foreign chemical manufacturers undersold them at such a price that they found they were unable to continue, and as soon as they were put out of business the foreigners raised their price. They have kept the trade ever since, for they have taught the American manufacturer the unfortunate lesson that if he were to establish an industry he could not continue it successfully, for the well-known methods of "dumping" large quantities on this market in addition to the meager tariff would soon teach them that they had better not try to make American goods again.

I believe I was the first one who pointed out to the Department of Commerce the shortcoming of our own laws. If a manufacturer in this country attempts to put a competitor out of business by what is known as unfair methods, all one has to do is to file a complaint with the Federal Trade Commission, and the matter is considered at once by its examiners and attorneys. But it is quite obvious that any law made in this country has no sanction against a foreign corporation outside of the jurisdiction of the United States any more than a firm in the United States can be held responsible for its actions according to the law of England, France or Germany.

Two weeks after the great war in Europe was under full swing, my firm recognized that a very interesting portion of its business would be obliterated if we could

PLANT OF DUREX CHEMICAL WORKS AT SWEETWATER, TENN.

not obtain barium compounds, and, to be exact, on the 14th of August, I started negotiations for a plant at Sweetwater, Tenn., for the purchase of a large tract of land containing the mineral barite, and in October, just a year ago, the first carload of barium salts was shipped from Sweetwater, Tenn., to our Long Island City works. From that day to this the plant has been working night and day. Additional mines have been purchased, additional installation has been erected, and the corporation is destined to continue to grow provided our own parsimonious and short-sighted Government will not aid in its final destruction.

There has been a great deal of talk about the dye industry in the United States, and any number of capitalists would invest the necessary funds to-morrow to establish a permanent aniline industry in the United States if they had some kind of assurance that the laws which prohibit unfair competition among ourselves could in some manner be made active as against those outside of the United States. There has been a tremendous amount of talk with reference to enacting an "anti-dumping" law. For months this has gone on, and up to now it is simply nothing but talk. A great deal of publicity has been given by public officials about the new and wonderful methods and short cuts that have been discovered for the manufacture of aniline dyes out of soft coal to such an extent that it has made the finest and best method for stock jobbing that has ever existed, but there isn't a color maker in the United States who can buy for immediate delivery the necessary aniline colors for the manufacture of the lake colors in any reasonable quantity in spite of all this caloric atmospheric discussion.

The barium industry in the United States is not an industry that can be started over night, and among the failures that I referred to, one of them was due to the fact that theory took the place of practice. The starting point of the barium industry in the United States is the admixture of barium sulphate and coal, both of which are finely divided, and heated, when the coal converts the entire oxygen into carbon dioxide, and leaves barium sulphide behind. The best that any man can do in practice is to get 70 to 75 per cent reaction. In our works we have had runs where we have gone as high as 85, but I think this is purely accidental, yet theoretically the reaction ought to be complete; and the difference between theoretical chemistry and chemical engineering shows that the chemical engineer must devise apparatus which will fit his raw material.

PILE OF ORE OUTSIDE FACTORY

*A paper read before the New York Section of the American Chemical Society, Chemists Club, October 8, 1915.

Not all barite is suitable for reduction. I have seen disastrous results where calcium fluoride was contained in the barite, and where certain forms of iron would actually produce a paralysis in the reaction, and if up to now I have had a slight measure of success in the manufacture of these compounds it is because I had a knowledge of the manufacture of these compounds prior to the European war.

Chemical engineering is 49 per cent chemistry and 51 per cent business acumen. I place the business end ahead of the chemical end for the obvious reason that ability to finance, ability to sell at a profit, and ability to organize are ahead of the chemical reactions involved. You can buy chemical talent, but you cannot buy business efficiency. You can buy barytes of any kind, but you cannot buy in the open market the skill necessary to design this apparatus so that the results will be uniform. I have seen a chemical industry fail because no commercial method of water purification necessary for the reaction was at hand, and if the subject had been carefully studied in advance a fortune could have been saved.

There are many arguments in favor of protection of the chemical industries in the United States, and what I say about the barium industry might refer practically to any other chemical industry, for we have economic differences between Europe and America which cannot be neutralized excepting by a system of protection in addition to an "anti-dumping" law. The freight rate from Tennessee to the coast on our raw material is about \$4.50 per ton. That is to say, barite cannot be shipped for less than that except by rail and water, which is a purely theoretical rate, for under existing circumstances a fifty-ton car of barium ore cannot be transferred to a steamer unless the material is packed in sacks or barrels. The same material pays \$1.80 freight from Bremen to New York, and I have it on very good authority that the rate from the mines of Germany to New York is \$2 per ton, because the German Government has always fostered its commerce by making special freight rates to export shippers.

The railroads in this country, which are, of course, all privately owned, show that they cannot carry trade for less than a fixed sum owing to their overhead charges; but their overhead charges, which start with the interest on their watered stock, are so great that the shipper must suffer. An eight-hundred-mile haul from Tennessee to New York pays \$5 per ton, and a twelve-hundred-mile haul from Missouri to New York pays \$4 per ton, and the one railroad can afford to do it and the other railroad cannot afford to do it. If the unsuspecting public is forced to support an overburdened railway, the Government should at least equalize this matter by giving us a protection in the form of tariff.

It is very amusing to read in the papers almost daily about wonderful new methods and new corporations who are about to manufacture all the dyestuffs in the United States and that the shortage of dyes and chemicals necessary for dyeing is about to disappear. It seems to be a pity that any Government employee will lend himself to the exploitation of what looks like stock jobbing schemes without due investigation, for I have not been able to buy any American dyes, and no one else that I know of has been able to buy any American dyes such as are generally used for the manufacture of lake colors. On the same sheet of the daily press in which these forthcoming industries are heralded you could invariably find a news item stating that the dye works are practically shut down for want of even simple dyes.

It is at once amusing and pitiable to note the super-

ficiality with which these investigations have been conducted. Some weeks ago in the *New York Times* there appeared a statement that a corporation was formed and very shortly there would be no dearth of the barium chemicals necessary for the manufacture of mordants and paper glazing material, and that a great deal of credit should be given to this concern as being the first concern to manufacture the barium chemicals in the United States, and this just exactly one year after the industry with which I am connected had been steadily turning out hundreds of carloads.

It may be true that I have not trumpeted from the housetops that the concern which we started was supplying material with great regularity and of chemical uniformity, and our own Government did not know it. On the other hand, last Spring a friend of mine sent me a clipping from the German commercial reports giving a full description of the materials that we are making, and an item concerning myself, for the investigator had stated that many German chemists would recognize my name as having been president of a section of the Eighth International Congress of Applied Chemistry. This was last Spring, and now our own wide-awake Government is noting the fact that soon there will be a barium industry started in the United States.

One of the very serious drawbacks concerning the new barium industry in the United States is the inability to obtain raw materials and equipment. There isn't a steel factory in the United States that is not working overtime at high prices on appliances which are designed to kill people, and as long as this condition obtains we peaceful manufacturers who want new rotaries and new apparatus will simply have to abide our time and pay exorbitant prices until we can obtain parts of new equipment.

To give you a striking example, we needed in one of our works a set of bevel gears made of a special metal, and after waiting twelve weeks, because there was no shop in the country which would pay any attention to

TYPICAL BARITE MINE SHOWING CHUNKS OF PROJECTING BARITE ORE

us, we finally had to devise gears ourselves as a make-shift. Nor does this apply to machinery alone, for no one could take any contract on any of the barium salts like the chloride, nitrate or sulphate and hope to deliver any part, because it is absolutely out of the question to obtain acids. The people with whom we have dealt for our acids for years are simply either refusing to give us any materials or supplying us with ridiculously small lots at enormous prices, for there are other channels which buy larger quantities and pay more than the peaceful manufacturer can afford.

I mentioned before that industrial chemistry was 51 per cent business and 49 per cent chemistry, and these figures will serve for an example. I was often asked why we located at Sweetwater, Tenn., and while I did not have very much time to look around I found that that was the logical and strategic location for coal, labor, water, and ore, for all of these materials combined are perhaps more reasonable at that locality than anywhere else I know of. In order to make a success of this enterprise the works should be located within such a radius of the mine that the ore can be delivered at a reasonable rate.

The great and only question with reference to the barium industry is whether this industry shall live after the European war is over, and I could not answer that categorically without some explanation. It depends entirely upon our own Government. If on account of the economic conditions which I have described, foreigners will be prevented from underselling us, we will be able to live.

Our own manufacturers should get together and understand that the underlying principle of successful business is to have a profitable business, for no argument is necessary on this point other than to prove that when you have a growing and going manufacturing concern, in order to have peace and success, you must be able to pay your men a living wage, and you must be able to pay them regularly, for the shutdown of any works in any community, particularly in a small one, produces disastrous results. Innocent women and children are made to suffer through it, so that in the greed of obtaining business manufacturers must understand that cut-throat methods lead to bad results for all parties concerned. I hope that when this war is over, the barium industry will be firmly established and protected, as the economic conditions in this country would demand.

What a remarkable difference there is between the enterprise in Japan as compared to the United States. Japan has suffered with a lack of chemicals and dye-stuffs just as much as we have, and both Houses of the Japanese Government have voted to subsidize all corporations and firms who are about to engage in the manufacture of chemicals and dye-stuffs that were not formerly made in Japan to the extent of three and one-half million dollars, the other half to be subscribed by the manufacturers themselves. It is understood that the subsidy granted is for ten years in order that the new manufacturing concerns may pay a dividend of at least 8 per cent. In addition to this it is understood that the Japanese Government has protected these manufacturers in the form of a high tariff. And that is the country to whom we have been sending missionaries in order to convert them from their archaic beliefs.

It seems to me that it is a great pity that nothing has been done up to now to protect the American manufacturer, for a subsidy from the Government is out of all reason, even though this is at present the richest Government in the world and Japan rated as one of the poorest. As I said before, we can only hope to succeed if our Government will help us from being destroyed by outside influences.

Theories of the Flotation Process

In METALLURGICAL AND CHEMICAL ENGINEERING, Sept. 1, 1915, page 571, we presented a complete description of the Callow pneumatic flotation process, giving flow sheet and several illustrations of actual operations. Since that time Mr. J. M. CALLOW has presented further operating data and certain theoretical considerations, embodied in a paper read by him at a meeting of the Utah section of the A. I. M. E., Salt Lake City, from which we excerpt the following:

Theories

So far no satisfactory explanation of flotation phenomena has been advanced. At my instigation and under my direction, a large amount of research work has been done in an endeavor to formulate some logical explanation of the phenomena, and perhaps to find some scientific way of conducting flotation experiments in place of the empirical methods now in vogue. Although the latter object has not yet been attained, still these experiments have resulted in the formulation of a theory that appears to be well grounded and that may prove of interest and value to others engaged in this art.

Much work has been done at the Mellon Institute at Pittsburgh under the direction of Dr. Raymond C. Bacon, and lately by James A. Block at the station of the U. S. Bureau of Mines in Salt Lake City. The result of all of this work is summed up in the following statement:

In considering the connection between flotation phenomena and the physical properties of the minerals concerned, there are two parallelisms:

1. It has been noticed for some time that the minerals which floated were not easily wetted by water, while those which were easily wetted did not tend to come up with the froth. This is the basis of about the only theory so far widely circulated; it was well stated by Hoover in his book, *Concentrating Ores by Flotation*.

2. There is a parallelism between certain electrostatic characteristics and the flotation properties of ores.

In the first-mentioned theory, surface tensions and contact angles should be considered. Certain minerals, such as galena, will float on the surface of still water, while gangue particles, since they possess a greater adhesive attraction for the water than the water's cohesive attraction for itself, will be drawn through the surface film into the interior, and sink because of their greater specific gravity. These properties of floatable minerals and gangues are increased by the presence of oil and acid. Oil sticks to galena with greater tenacity than it does to silica, and an oil surface is still less easily wetted than a galena surface. The acid in the water causes a still greater difference in the various surface tensions. This, it seems, is without question the explanation of the action in the MacQuisten process, in which the ore particles are lifted to the surface, where they can be removed by skimming off the surface layer of the liquid.

With reference to the second parallelism, it has been noticed that extremely small amounts of certain colloidal impurities, such as saponin or tannin, were detrimental to flotation; while others, such as Congo red and methylene blue, did not interfere, and were, if anything, beneficial. In classifying these, the injurious ones generally came under the head of what physical chemists call electronegative colloids, while electropositive colloids were not harmful. Suspended particles will generally migrate when placed in an electric field, and this classification comes naturally from the direction of their migration. This migration is called electrophoresis, or electrical endosmosis, and is the result of the formation of contact layers around the particles by the liquid

containing them, very similar to the formation of surface films when liquids come in contact with air. These contact films almost invariably have a difference of potential between their inner and outer surfaces. An air-water contact film has, for instance, a difference of 0.055 volts, and other contact films have similar charges. This causes the particles to act like charged solids, and to be attracted by electric charges of opposite sign.

The charges on solids and non-miscible liquids can be conveniently studied on the stage of a microscope.

This work naturally led to the study of the charges exhibited by various ores and minerals, and in that work an interesting parallelism was observed, namely, that floatable minerals seemed to have positive charges, and non-floatable gangues negative charges. Some gangues were found with positive charges, but they were characteristically hard to handle, having a tendency to come up with the froth. These charges sometimes vary with the acidity or alkalinity of the liquid, and this variation is not inconsistent with the effects of acidity or alkalinity on the flotation of ores.

It has been noticed that these electrostatic properties depend on the condition of the surface of the particle and not upon the composition of the mass. For instance, lead oxide which is ordinarily negative, or neutral, when covered with a sulphide coating, takes upon itself a positive charge.

Recent investigations on the coagulation and deflocculation of slimes, on the coagulation and dispersion of colloids, and along similar lines, show that these contact film charges, although small, have an important bearing on the dispersion or coherence of particles suspended in liquid mediums. In fine suspensions and in colloidal solutions, these charges may often be neutralized by the introduction of oppositely charged ions, precipitation generally taking place whenever these charges fall below certain limits. Oppositely charged contact films have a general tendency to coalesce, while similarly charged films, if their charges are great enough to overcome natural cohesiveness, do not seem to coalesce, but to repel each other, and if the weight of the particles is small enough in relation to their size and surface, permanent dispersion will take place, the particles distributing themselves through a liquid in much the same manner that gas will fill a container.

In view of the above observations, it seems possible that flotation is the result of difference in polarity in the charges on the various ore particles, and on the bubbles. Since oil contact films and air contact films have both been proved to have negative charges, the positively charged minerals will adhere to either. The bubble mantles in a flotation machine are undoubtedly composed of oil, or of oil in emulsion, since pure water alone will not froth. The same forces, then, that cause oppositely charged colloids to agglomerate and precipitate, cause the minerals to adhere to the oil-covered bubbles, and the same forces that keep the particles of an oil emulsion dispersed, keep the gangue particles repelled from the bubbles.

Expressed briefly, the theory is as follows:

That oil flotation is an electrostatic process. It is a scientific fact that when a solid particle is suspended in water, the water will form around the particle a contact film which generally possesses an electric charge, the amount and polarity depending upon the nature of the surface of the particle and the electrolyte in which it is suspended. The presence of these charges can be demonstrated by the fact that the particles possessing them will migrate when placed in an electric field. It has been demonstrated that floatable particles have charges of one polarity (positive), and that non-floatable particles have charges of the opposite polarity (nega-

tive); that the froth is charged negatively and so attracts the positively charged or floatable minerals, and repels the negatively charged or non-floatable ones. It is this, it is believed, that causes the floatable minerals, galena, sphalerite, etc., to adhere to the froth, and the gangue minerals, silica, etc., to remain in the liquid where they can be discharged as tailing.

In the discussion which followed Mr. Callow's paper Mr. JAMES A. BLOCK said that during the last few months he has tested about fifty samples of ores, etc., the flotation characteristics of which he knew. Some of these were samples of froth and tailings from plants in actual operation, but most of them were samples taken from laboratory tests going on at the plant of the General Engineering Company, and at the station of the U. S. Bureau of Mines, Salt Lake City. In all of these experiments, no real exception to the theory was found. All of the tailing samples produced in actual flotation showed a negative polarity; all of the ores with the so-called "bad gangues," except one or two, showed some positive polarity, and these exceptions could be explained by the extreme dryness and scaliness of the gangue minerals, and all of the froth products showed positive polarity when the samples were fresh. It was often true that after standing some time these froth samples would reverse, especially when they contained considerable oil, but this reversal can be explained if we assume that the oil forms a coating around the particles upon standing.

The question might naturally be asked, "Can these electric charges be put to any practical use?" A machine used to purify clays employs very similar charges on the constituent particles of clay. This machine (see Fig. 1) consists of a revolving cylinder, made of conducting material, such as iron, about half immersed in a clay pulp in a trough. At a distance of about $\frac{1}{2}$ in. from the immersed side of the cylinder is a coarse wire screen. A direct current of about 50 volts was applied to the cylinder and the screen, the cylinder being the anode and the screen the cathode. The cylinder attracted the negatively charged kaolin, while the screen attracted the positively charged pyrite, ferric hydroxide, and aluminium hydroxide. It was found that a product running only about 17 to 20 per cent moisture could be scraped off the upper side of the cylinder, which revolved slowly, while the impurities fell through the screen to the bottom of the trough.

The objection to the process was the high cost of the power needed, which averaged over 30 cents per ton of product, but the process is undoubtedly of interest in that it shows that these electrostatic charges are de-

⁴Transactions of the English Ceramic Society, vol. X11, pp. 36 to 64 (1912-13).

FIG. 1—APPARATUS USED IN PURIFYING CLAYS

a. Revolving cylinder. b. Wire screen. c. Wood trough. d. Clay pulp.

pendable enough to be put to practical uses. It is also of interest in that the polarity of the charges noticed on various minerals checks the results of the experimental work upon which the theory is based.

Mr. OLIVER C. RALSTON of the Bureau of Mines (Salt Lake City Station) said that for some time he had had a growing conviction that possibly the particles dealt with in the flotation of sulphide minerals were acting according to certain laws laid down in colloid chemistry. One of the characteristic things about either suspension or emulsion colloids is that their individual particles are charged with one or the other sign of static electricity. It is known that the amount and signs of these charges can be controlled by the amount and character of electrolytes put into the water in which the colloids are dispersed, and in turn the properties of the colloidal suspension are greatly changed with this change in the electric charges on the particles. The question has been whether the comparatively coarse suspensions of ore can be compared with suspension colloids, or whether they were too coarse to allow the electric charges on the suspended particles of mineral to produce any measurable effect.

"This question has been answered fairly definitely in my laboratory during the past year, for it was found that the electric charges on the particles of what we call 'slimes' and 'fines' are of considerable importance in the control of the rate of settling of such slimes in water. With this much definitely settled, and with a great amount of literature available in the realm of colloid chemistry dealing with the electric charges on particles of such things as quartz, galena and sphalerite, and on oil droplets and air bubbles, it was easy to find a combination of circumstances which might explain flotation from this new viewpoint. At about this time George W. Riter made the prediction that the depths of electrostatics would have to be thoroughly sounded before flotation phenomena could be entirely understood. He seemed to have the idea at that time that the charges on the particles were generated by friction in the flotation machine, in much the same way that a piece of sealing wax becomes charged when rubbed with flannel; but we know from colloid chemistry that these charges of electricity arise whenever two substances of unlike dielectric constants come into contact.

"Further work along the line of controlling the charges of the ore particles, thereby controlling the rate of settling of the particles in water, has convinced me that the charges are of considerable importance, and the results of this work will be reported soon. Mr. Callow told me last spring that he had much the same conception of the matter as I, and had the Mellon Institute in Pittsburgh working on it for some time. Mr. Callow sent a man to the Salt Lake laboratory of the U. S. Bureau of Mines to try out some methods of measurement which I had proposed and which had not been used in Pittsburgh; some of the results are presented in Mr. Callow's paper.

"The knowledge that when flotation conditions are good the froth has a positive charge and the rejected gangue a negative charge, that the oil droplets and the air bubbles are negatively charged, and the sulphide particles positively charged, is highly interesting. We have here electrical effects which are parallel to flotation phenomena, and the conclusion that they are connected with each other seems justifiable. Just exactly how they are connected is not yet clear and may prove difficult of solution.

"It is to be hoped that further work will be done along this line in order that a theory of flotation may be found, which will afford a more rational control of flotation testing, and an extension of the process to the treatment of any kind of minerals."

Radium from Carnotite

On the evening of Friday, Dec. 17, Dr. Charles L. Parsons, chief of the Division of Mineral Technology of the Bureau of Mines, lectured at a meeting of the New York Section of the Society of Chemical Industry on "Extraction and Recovery of Radium, Uranium and Vanadium from Carnotite." Dr. Wm. M. Grosvenor, chairman of the Section, presided.

Dr. Parsons' lecture was particularly interesting on account of the exhibit and demonstration of various samples of radium, as well as lantern slides and moving pictures. After the lecture there was some discussion in which representatives of the Standard Chemical Co. participated. The discussion was good natured and dealt especially with the applicability of the process to ores of less than 2 per cent U_3O_8 , and the cost and price of radium and the policy of the Bureau of Mines in dispensing with the radium produced in connection with the National Radium Institute (see account below). A leading official of the Memorial Hospital of New York paid a very high tribute to Dr. Parsons' eminent business ability in running the radium factory and gave some information on cancer treatment by radium.

A very full account of the work of the Bureau, done in co-operation with the National Radium Institute, has since appeared in Bulletin 104 of the Bureau of Mines, entitled *Extraction and Recovery of Radium, Uranium and Vanadium from Carnotite*, by Charles L. Parsons, R. B. Moore, S. C. Lind and O. C. Schaefer. (124 pages, with many illustrations.)

As the general method of treatment, used by the bureau, has already been described in our issue of Dec. 15, 1915 (Vol. XIII, p. 965), we give here only some supplementary information on interesting details.

The capacity of the plant is $3\frac{1}{2}$ tons of ore per day, and up to Oct. 10, 1915, nearly 5 grams of radium element had been extracted and approximately $2\frac{1}{2}$ grams of element delivered in the form of radium bromide of such a degree of purity as was desired by the hospitals concerned (the Howard A. Kelly Hospital

FIG. 1—FLOW SHEET OF RECOVERY OF RADIUM FROM CARNOTITE

in Baltimore and the General Memorial Hospital in New York).

"With ore obtained from Government land or produced at a cost as low as that maintained in the operations of the bureau, it has been shown that the cost of producing radium need not exceed \$40,000 per gram and that the extraction of at least 90 per cent of the radium present may be obtained from good-quality ore, such as the bureau has been able to procure.

"The market price of radium for some two or three years has been \$120,000 and up per gram of element according to purity. At the time of the beginning of the European war there were 16 to 20 grams of radium contracted for abroad, chiefly in Germany, at prices above \$120,000 per gram. Seemingly the war has not affected the market price, but simply the amount produced. As to the selling price of radium in the future, the bureau makes no prediction, but it does not follow that the selling price will decline because of the development of cheaper methods of production. Rather is the case somewhat analogous to the production of gold, diamonds, or any other material that is in steady demand but occurs only in very small quantities. Beyond doubt, the amount of radium in nature is exceedingly small. Other deposits of radium ores may be found, but it is highly improbable that the rarity of uranium ores will ever be greatly modified, so that the price of the finished material will largely depend on the ability to procure the raw material.

"According to the best evidence that the bureau can obtain, and it has investigated the matter carefully, there is not sufficient ore available to maintain for many years even the rate of production of 1914. In this connection it should be remembered that the radium produced by the National Radium Institute is not for sale nor for distribution. The Radium Institute was organized for the purpose of studying the curative properties of radium and not for private gain. The radium produced is being used in two hospitals, the Howard A. Kelly Hospital in Baltimore and the General Memorial Hospital in New York."

According to the agreement between the Bureau of Mines and the National Radium Institute any radium produced in excess of 7 grams of anhydrous radium bromide (RaBr_2) from any 1000 tons of carnotite ore may be donated to the bureau for further experiment and study. This excess output will be supplied to the hospitals of the Army, Navy and Public Health Service.

The ore treated by the Bureau contains 2 per cent or more of U_3O_8 . In considering the work it must be taken into consideration that the problem is to get one part, by weight of radium, out of 200,000,000 parts of ore. This concentration process becomes possibly only by making use of electrical measuring methods by which radioactive elements can be detected and quantitatively measured in quantities far below the limits of any methods based on other properties.

The method of treatment of the bureau (nitric acid leach) is new. Older methods (leaching with sulphuric acid or hydrochloric acid and fusion with sodium sulphate or sodium carbonate) are discussed in the bulletin. If radium is the principal product desired, the nitric acid leaching method is the most direct and efficient. The cost of the nitric acid process is considerably reduced by the fact that sodium nitrate is recovered with small loss and nitric acid once more made from the sodium nitrate, so that the process is cyclic with respect to nitric acid.

In the nitric acid process the radium is at once recovered as a high-grade radium barium sulphate, practically free from silica, and easily treated by improved methods. The process is adapted to recovering

FIG. 2—SECTIONS OF LEACHING POT, FILTER, AND DETAILS OF LEACHING-POT STOPPER

either the radium by itself, or the radium, uranium and vanadium, as the radium is obtained first, and from that point all the other products may be discarded without further treatment, if so desired.

The different steps are each completed in one day, the equipment is not expensive, the extraction and recovery are high, and it is believed that the costs are lower than those with any other process for treating carnotite.

Fig. 1 gives the flow-sheet of the whole process, the different steps of which were already described on page 965 of our issue of Dec. 15, 1915.

Fig. 2 shows sections of the leaching pot, filter, and, at the right, details of the leaching pot stopper. The amount of acid used for leaching is 121 lb. of 100 per cent nitric acid to 500 lb. of ore, the acid being diluted to 38 per cent strength. However, the strength may be varied somewhat, ores high in sulphates requiring stronger acid. The acid is brought near the boiling point by live steam, which has been passed through a baffle in order to eliminate any impurities from the steam. The ore is then run in, being stirred with a wooden paddle during the process. The acid is heated for 15 min. longer, with occasional stirring, and the acid is then run into an earthenware vacuum filter, asbestos filter cloths being used. As much as possible of the sand is held back in the pot by means of a long wooden plug manipulated by hand, and this sand is given an acid wash with acid about one-third of the strength of that used for the first leaching. This sand is then dumped on the filter, and receives two washings with hot distilled water.

Synopsis of Recent Chemical and Metallurgical Literature

Iron and Steel

Electric Furnace Steel in Canada.—In the discussion of a paper by Dr. A. Stansfield, read before the Montreal Metallurgical Association, Mr. J. E. DAVEY, superintendent of the Canadian Brakespur Co., of Sherbrooke, gave the following description of his company's installation.

"We have in operation at Sherbrooke four 5000-lb. basic-lined, three-phase furnaces, and one 2000-lb. furnace. The dimensions of the 5000-lb. furnaces are 70 in. by 108 in. outside lined down to 34 in. x 72 in. wide, while the smaller furnace has a circular hearth of 36 in. in diameter. All the furnaces are mounted on rockers and tilt to pour their charge. We found it very difficult to construct a roof that would withstand the heat of the electric furnace, but finally laid some $\frac{3}{4}$ -in. water-cooled pipes across the furnace and built a roof of silica bricks resting on these pipes. The electrodes are also water jacketed at the point where they enter the furnace, by four coils of $\frac{1}{2}$ -in. pipe. The electrodes are made of 6-in. graphite rods, in 4-ft. lengths, which are threaded and joined together to make one continuous electrode. These are raised and lowered by means of steel wire wound on a drum, passing over a sheave and insulated from the electrode holder, but the electrodes are somewhat unsteady, which causes short-circuiting in the furnace when melting down the scrap. It is intended to install rigid holders so that the electrodes will be raised and lowered in a vertical line. The electrodes for the 1-ton furnace are 4 in. in diameter.

"Each of the larger furnaces is provided with a 500-kw. three-phase transformer which receives the electric current at 6600 volts and delivers it to the furnace either at 40, 70 or 100 volts. The 70-volt connection is usually found the best, as 40 volts would be too low, and with 110 volts the furnace would be difficult to regulate. An ideal arrangement would be to have a transformer to give about 60 volts during the breaking down period, with means for raising this to about 90 volts after the charge has been melted. The transformer is placed as close as possible to the furnace. The cables from the transformer to the top of the furnace are 32 ft. in length; part being flexible to allow of the movement of the electrodes. The cables are composed of fifty No. 6 wires, and the three cables for each furnace are interlaced to reduce inductance losses. The cables are carried overhead, instead of in a conduit, as they are more accessible in case of an accident to the insulation.

"In making a 5000-lb. heat, 2000 to 3000 lb. of scrap, etc., are charged through the doors, which are in the roof, and when this material is melted the remainder of the charge is added to make a total of 5250 lb., thus allowing for the loss of about 4 per cent of the metal. The melting occupies from $4\frac{1}{2}$ to 5 hr., and is followed by refining. A considerable reduction of both carbon and sulphur is effected during the melting, the sulphur being easily reduced to 0.04 per cent or 0.03 per cent, and by means of an oxidizing slag the phosphorus is reduced to 0.02 per cent. The specification limits the carbon to 0.55 per cent, the silicon to 0.30 per cent and the sulphur and phosphorus to 0.05 per cent each, while the manganese must be between 0.40 per cent and 1.0 per cent. The power consumption per ton of molten steel in the ladle is about 600 kw.-hr.; the cost of refractories is about \$2.60, and of electrodes \$2.70 per ton of steel. The molten steel from the furnace is poured into a ladle and the ladle is car-

ried by a 4-ton trolley crane to a turntable, on which are placed enough ingot molds to take the contents of one furnace.

"Although these furnaces, which have been designed and constructed by the Brakeshoe Company, do very satisfactory work, there will be installed by the end of October a 2-ton Snyder single-phase furnace. This is guaranteed to give ten heats of two tons each in 24 hr. and is expected to give twelve heats of 5000 lb. in 24 hr. This furnace has one 5-in. graphite electrode entering the roof, and a steel column passing through the basic lining and the furnace bottom. The electric current is supplied at 220 volts from a substation placed on the other side of a wall. The cables pass through a conduit to the electrode holders. The electric arc varies from 14 to 18 in. in length."

Gold and Silver

Treatment of Antimonial Gold Ore.—According to the *South African Mining Journal* of Oct. 9, 1915, the problem of successfully treating antimonial gold ore on the Murchison Range has been solved by a process introduced by McArthur Forrest & Company. In brief the process consists in dissolving the antimony sulphide from the crushed ore with a hot solution of caustic soda, recovering this constituent as a saleable product and cyaniding the residue for gold. At the United Jack property the process is as follows: The ore is crushed in ball-mills to 30-mesh and delivered to vats 23 ft. in diameter and 8 ft. deep. Caustic soda solution is then pumped on the pulp and leaching is conducted as in cyanidation. The resulting solution is treated with carbonic acid gas from a lime kiln, which precipitates the antimony sulphide in an amorphous condition. The mixture is filter-pressed and the resulting cake marketed. The solution is returned for further use. The sand residue, containing gold is then cyanided in the usual manner. The original ore is reported to contain gold to the value of \$7 to \$8 per ton and about 12 $\frac{1}{2}$ per cent antimony sulphide.

Copper

Pyrite Smelting at Mount Lyell.—In his address as president of the Australasian Institute of Mining Engineers, Mr. ROBERT STICHT has given the most interesting and instructive account yet published of the smelting practice at Mount Lyell. The address appears in full in the Society's *Proceedings*, No. 19. Introducing his remarks by saying that pyritic smelting is something "in which doing is decidedly more difficult than speculating on the 'underlying principles,'" the author proceeds to outline "how it is done" rather than "why it works." We give herewith his "mental picture" of the process, leaving some other details for further presentation.

"In order to understand our method, it is necessary to form a correct mental picture of the inner appearance and working condition of the pyrite furnace. Its most salient feature is a pronounced openness or porosity of the masses in action, together with a total lack of stratification or bedding, yet with an even distribution of the various components of the charge throughout each horizon. There is no layer-like arrangement of the different materials, and no alternation of charge and fuel. There is no reducing zone, but an oxidizing one, restricted, like the first-mentioned, to the lower regions of the column. In distinction from the ordinary furnace, in which a distinct reducing zone precedes the slag-forming zone, the oxidizing and the slag-forming zone are identical. From top to bottom, however, there is one element of the charge present everywhere, which forms the skeleton, so to say, of the

furnace-body in action. This element is the *free silica* in charge. The lumps of quartzite, etc., are present in excess of the quantity required for the momentary furnace action, and they build up a honeycombed or vesicular column, reaching from the crucible of the furnace upward to the stock-line, or top of column. This silica skeleton is a necessity. Without it pyrite smelting is unthinkable. It forms a physical structure like an aggregate of cells, each cell in the heart of the furnace forming a little Bessemer vessel with silicious walls. The wasting away of the material of the walls with scorification does not unsettle the fixity of the column, for the lumps of silica are constantly being replenished by new ones settling down from above.

More particularly, the furnace column may be divided into three regions—an upper preparatory one; a central one, where the entire chemical activity takes place; and a lower one, extending from above the tuyeres to the bottom of crucible, in which no action takes place. The first contains the charge undergoing only primary chemical and physical changes, the second is the seat of oxidation and scorification, and the last only forms a passageway and receptacle for the molten products. The most important region is the central one. It is situated some distance above the tuyeres, much higher up in the shaft than the slag-forming zone of the ordinary furnace, and fluctuates up and down in position in accordance with the variations in the pneumatic conditions within the shaft, its location being principally decided by the volume of blast blown in. To characterize it as that part of the shaft or column in which the vital functions of the pyrite furnace are in play, I have designated it the 'focus.' The three zones doubtless merge into each other, the lower preparatory zone and the upper reaches of the focus probably not being clearly defined. The lower margin of the focus, however, is probably sharply divided from the basal region. The furnace activity is all upwards, not downwards, the sinking of the fused products and the silica excepted.

The preparatory zone is probably not so high as in the ordinary furnace, and has the usual functions of driving out moisture and preheating the masses by means of the escaping gases. It has also a very special one, in the case of the pyrites, without which the further furnace action would not take place as it does. This consists in the sublimation of the volatile sulphur atom out of the pyrites, at the top of the zone, and the fusion and superheating, lower down, of the residuum, the composition of which, through the loss of about three-sevenths of the total sulphur, is practically that of pyrrhotite, FeS_2 .

In this uppermost zone no chemical action affecting the ores on charge takes place, and heat is only being absorbed, but it appears that within this zone a chemical interchange is enacted, accompanied by the evolution of a small amount of heat, between the heated sulphur dioxide, coming up from below, and the coke fed in, as soon as the latter sinks to a horizon where it is hot enough. If the amount of coke is small, it probably does not survive this reaction, and no coke gets down to the focus. Should the amount of coke be large, then some may reach the focus, but it will necessarily interfere with the reactions there, and spoil the pyritic work. A small amount of coke on charge is, however, still a *sine qua non*, and seems required to support the work going on in the preparatory zone, even though its thermal effect is low, under the circumstances. As soon as the melting point of the pyrrhotite residuum is reached in this zone this substance melts, and we now have the phenomenon of an incandescent, honeycombed mass of silicious material in lumps, in the in-

terstices of which aggregate the molten sulphide courses downward, towards the focus, in a heavy shower.

The atmosphere in the preparatory region consists only of the neutral gases forming the products of combustion from the focus, and the CO , out of the limestone and coke, and is heavily charged with sulphur vapor, derived from the disintegrating sulphide of iron and the reaction between coke and sulphur dioxide. By far the chief constituent is nitrogen; then follow sulphur dioxide and carbon dioxide. There is, or should be, an absence of oxygen, and consequently no roasting or other oxidizing action can take place in this zone. In the lower portion of the preparatory zone the limestone may be calcined, but this is more likely to be completed in the upper regions of the focus.

Physically, the preparatory zone represents a mere jumble of charge constituents undergoing certain changes. Yet the distribution of the constituents should be homogeneous and properly balanced, otherwise the furnace will not work well. Occasionally it may be necessary temporarily to disturb this regularity of mixture by placing more pyrites, or more silica, or more slag, here or there, for the purpose of curing irregularities in the descent of the masses, to relieve the beginning formation of accretions, or to close blow-holes, etc., but even this treatment, though of a curative nature, cannot be persisted in too long."

Recent Chemical and Metallurgical Patents

Detinning

Electrolytic Detinning.—In the alkaline electrolytic detinning process it has heretofore not been possible to construct an apparatus made up of a plurality of cells connected together owing to the difficulty of circulating the electrolyte and of preventing the supply pipes from becoming plated with tin, thereby reducing their inside diameter. The process has, therefore, been carried out in single cells. According to a patent of Dr. HANS GOLDSCHMIDT of Essen, Germany (assigned to Goldschmidt Detinning Company of New York), it is now possible to carry out this process in a large number of cells, connected in series with each other, to maintain a good circulation of electrolyte, and also to prevent the circulating pipes from becoming plated with tin. This is accomplished, as shown in Figs. 1 and 2, by providing a reservoir tank 1 above the electrolytic vats and connecting this tank with the vats by a series of pipes as shown. The pipes are made of decreasing diameter as they approach the vats, as this has been found to be very important in providing a good flow. The ends 27 of the pipes, which supply the fresh solution from the high tank, do not touch the liquid and are made of rubber, thus preventing any possibility of becoming obstructed due to tin coating. Each cell has its own

FIG. 1—ELECTROLYTIC DETINNING SYSTEM

inlet and outlet pipe directly connected to the large tanks. The lower tank 36 receives the outlet, and it is pumped from here to the upper tank.

A temperature of 70 to 80 deg. C. is maintained, and a high current density, 800 to 1000 amp. per square foot,

FIG. 2—ELECTROLYTIC DETINNING SYSTEM

is used. The electrolytic vats are made of cast iron encased in wood and form the cathodes. The anodes are usually in the form of a basket containing the material to be detinned. The solution used for the electrolyte is a mixture of stannate of soda and caustic soda with an excess of caustic soda. Carbonic acid from the air is taken up, forming sodium carbonate. The process is continuous as the electrolyte is regenerated, as it is circulated through the system (1,160,400 and 1,160,401, Nov. 16, 1915).

Detinning Process.—A rather novel process for removing metallic coverings from other metals, such as tin from tinned steel scrap, is patented by Dr. HANS FOERSTERLING and HERBERT PHILIPP of Perth Amboy, N. J. (assigned to Roessler & Hasslacher Chemical Company). This process depends on the alloying properties of alkali metals with other metals, such as tin, and as

FIG. 3—SODIUM PROCESS OF DETINNING

applied to detinning it consists in treating the tin scrap in a heated container with molten sodium. In Fig. 3, numbers 1, 2, 3, 4 and 5 represent iron vessels provided with drain pipes a_1, a_2, a_3, a_4, a_5 and vacuum pipes b_1, b_2, b_3, b_4, b_5 . A common pipe C connects all the drain pipes and a common vacuum pipe f leading to a vacuum pump connects the separate vacuum pipes. Stop cocks are provided on all pipes. In conducting the process all the vessels are placed in one furnace as a unit and heated by the gas burner m . Vessels 1, 2, 3 and 4 have openings k in the top, and vessel 4 has a removable cover and a revolving basket h inside, rotated by shaft i and wheel j . When the process is running, vessel 3 will contain a 25 per cent tin-sodium alloy, vessel 2 a 5 per cent tin-sodium alloy, and vessel 1 pure sodium. The temperature is maintained at about 400 deg. C. The basket h is filled with tin scrap and the cover put on. The vessel is then evacuated, the vacuum shut off and the alloy from vessel 3 allowed to run in. The basket is

then rotated, when the tin from the scrap alloys with the sodium very quickly. A vacuum is then created in 3 and the alloy run back again. In like manner the tin scrap is treated with the weaker tin-sodium alloy from 2, and then with the pure sodium from 1, after which the scrap is removed and fresh scrap put in. After the alloy in 3 has reached 50 per cent it is conveyed into vessel 5, when it may be led away through pipe n for distilling off the sodium and recovering the tin. The alloy from 2 is run into 3, the alloy from 1 is run into 2, and fresh sodium placed in 1. Thus a continuous process is formed. The rapidity of action of the sodium is noteworthy. The following table shows the time required:

Alloy	Per Cent Tin in Scrap Start	Per Cent Tin in Scrap Finish	Time, Min.
60 tin 40 sodium.....	1.8	0.44	10
50 tin 50 sodium.....	1.8	0.22	10
40 tin 60 sodium.....	1.8	0.13	10
30 tin 70 sodium.....	1.8	0.015	10

"The residual iron when removed from vessel 4 still contains traces of sodium, and when molten shows a superior quality over ordinary iron" (1,160,590, Nov. 16, 1915).

Electrolytic Furnaces

Manufacture of Amides, Cyanamides and Cyanides.

—A continuous process for the electrolytic production of amides, cyanamides and cyanides is patented by Edgar A. Ashcroft of London, England. This process is based on his previous patent (801,199, Oct. 10, 1905). The reactions taken advantage of are those of ammonia and metallic sodium forming sodium amide between 120 and

FIG. 4—DIAGRAM OF PROCESS

the anode for the production of amide, cyanamide or cyanide. The electrolyte used in the second cell is made up of the product which it is desired to obtain. For instance, for producing sodium amide, an electrolyte of sodium amide is used, and as ammonia gas is conducted in more sodium amide is formed, which continuously augments the electrolyte. The sodium amide is tapped from time to time as produced. It is possible in making sodium amide to use a solution of the raw materials in the first cell and a mercury cathode, but in making sodium cyanamide a mercury cathode is not suitable. In making cyanamide the procedure is the same as in making amides except that carbon is added to the electrolyte in the second cell to react with the amides as

fast as formed and the higher temperature is needed. In making cyanide the temperature is raised further to about 800 deg. and an electrolyte of cyanide is used. The depleted alloy is returned to the first cell for reuse. It is claimed that the process is more economical and efficient than previous processes (1,163,498, Dec. 7, 1915).

Manufacture of Sodium Alloys.—In electrolyzing fused caustic alkalis for producing alkali metals using insoluble anodes, it has generally only been possible to obtain half the current efficiency owing to one molecule of the alkali out of every two formed being required to decompose the water formed by the reaction, $2\text{NaOH} = 2\text{Na} + \text{H}_2\text{O} + \text{O}$. In order to increase this efficiency, EDGAR A. ASHCROFT of London, England, proposes to use a higher temperature and provide for the escape of oxygen and steam, instead of oxygen and hydrogen. Further features of the process are the maintaining of only a thin layer of the alkali hydroxide above the heavy metal alloy cathode, and the agitation of the electrolyte and alloy cathode by a pump and magnetic stirring device and the use of a higher current density at the anode. The process is carried out in a copper-lined or nickel-lined cell, either singly or in conjunction with a secondary cell, for the production of amides, cyanamides, or cyanides. An annular plate of nickel is used as anode. The temperature used is between 400 and 500 deg. C., as compared with 330 deg. in previous processes, and efficiencies of from 60 to 80 per cent are claimed. The process is suitable for employment in large units and currents up to 10,000 amp. may be used in a double cell (1,161,585, Nov. 23, 1915).

Apparatus for the Manufacture of Sodium and Sodium Alloys.—In processes for making sodium by electrolysis of a fused mixture of sodium and potassium chlorides with a molten lead cathode, it has heretofore been difficult to produce sodium free from potassium, due to potassium alloying with the sodium and lead in the primary cell and passing into the final product. In an apparatus patented by EDGAR A. ASHCROFT of London, England, these difficulties are claimed to have been overcome. Reversible reactions, such as the following, have been found to occur between the electrolyte and alloy in the primary cell and between produced alkali metal and electrolyte in the second cell:

It has been found that these reactions may be controlled in such a way as to produce sodium which is practically free from potassium. The second reaction takes place more readily from left to right, and this fact may be made use of by electrolyzing a mixture of 40 per cent sodium chloride and 60 per cent potassium chloride and forming the lead-sodium-potassium alloy as usual. This alloy is then separately heated with a fresh electrolyte of NaCl, which removes the K from the alloy. The chlorides are then conducted to the first cell and the alloy free from K to the second cell for further use. This "triple" procedure has been found unnecessary, however, in most practical cases, and the following procedure has given a good product: The electrolyte in the first cell, consisting of sodium chloride with 2½ per cent or less of potassium chloride, is kept in whirling motion by creating a magnetic field around the cell by a metallic conductor. The anode is a hollow graphite cylinder placed at the center so made as to carry off the chlorine generated which is forced toward the center by the whirling motion. The first or primary cell is lined with a basic insulating lining as a temperature of about 750 deg. C. must be maintained (molecular proportions of sodium and potassium chlorides melt at 670 deg. C.). The whole apparatus is cast in one piece of

steel, and another feature is the addition of an intermediate receptacle for the alloy connected by weirs and overflows to both cells so that changes in bulk will not affect the continuous operation of the cells. The alloy flows continuously from the first cell into the intermediate receptacle, and is pumped or flows from there into the second cell as required, a constant level being always maintained. Passages are also provided for conducting the depleted alloy back to the first cell (1,159,154, Nov. 2, 1915).

Manufacture of Cyanides and Cyanamides.—An electrolytic process for manufacturing cyanides and cyanamides is patented by CHARLES E. ACKER of Ossining, N. Y. (assigned to Nitrogen Company of New York). In an electrolytic furnace 1 (Fig. 5) of cast

FIG. 5—ELECTROLYTIC FURNACE FOR CYANIDE PRODUCTION

iron or steel there are a primary chamber 4 and a secondary chamber 5, partially separated from each other by the wall 2 of refractory material. The anodes 8 are of carbon and the cathode 13 is of iron, nickel or carbon. The electrodes are adjustable. The chambers 4 and 5 are closed at the top by covers 9 and 12. The primary electrolyte consists of molten barium chloride with a small amount of sodium chloride at the beginning of the operation. The secondary electrolyte consists of molten sodium cyanide. Both electrolytes rest on a bath of molten lead shown at 16. In starting the process the electrodes are raised slightly above the surface of the lead before turning on the current. Barium and sodium are liberated in the primary cell, an alloy of lead, barium and sodium being formed. This alloy is put into circulation by means of a centrifugal pump and soon becomes homogeneous and of uniform temperature. In the secondary chamber, in which the lead-barium sodium alloy is the anode, the barium combines with CN ions set free by electrolysis, forming barium cyanide. Metallic sodium is liberated at the cathode, which reacts with the barium cyanide, forming sodium cyanide and barium. Charcoal is introduced through hopper 22, having first been exhausted of its air by a pump. The barium set free by the metallic sodium combines with the carbon forming barium carbide, which remains suspended in the cyanide. Either ammonia or atmospheric nitrogen is then introduced through pipe 19, passing down through cathode 13, or through pipe 21, directly to the molten metal. The latter pipe is used when it is desired to preheat the nitrogen-containing gas by means of the molten metal, as in the case of air. The nitrogen then combines with the barium carbide forming barium cyanide, and thus a cyclic process is formed. As soon as sufficient barium has been added to the process through the primary cell it is unnecessary to add more, and the primary electro-

lyte may consist only of sodium chloride. When enough cyanide has been formed the charge is clarified by stopping the flow of gas first, then the liberation of sodium, and allowing the mass to settle. Barium carbide with the excess carbon will settle and the cyanide may be tapped off, or the sodium supply may be cut off and the product drawn off as a mixture of barium and sodium cyanides (1,160,811, Nov. 16, 1915).

Blower for Flotation and Smelter Work

A blower which meets successfully the requirements of flotation and smelter service in which the air supply is so essential a consideration, is shown in the accompanying illustrations. This blower is known as the Boston type blower and is made in various sizes, according to capacity and pressure desired, by the Connersville

FIG. 1—BOSTON TYPE BLOWER

Blower Company, Connersville, Ind. It is rationally designed for high-pressure work and has found much application in smelter and flotation work. Fig. 1 shows the blower complete and Fig. 2 shows the interior construction and principle of its operation. The rotating parts, called impellers, do not come in contact with each other or with the case at any point in the revolution. They are finished all over with at least two cuts and are separated by accurate clearances so that there is no internal contact or wear and no need for internal lubrication. The impellers are symmetrical, carefully balanced and heavily ribbed internally. They are pressed and keyed onto the shafts and may be operated at high speeds without vibration.

The losses of a positive pressure blower are confined to mechanical friction and slippage. The slippage loss is determined by the pressure, regardless of the speed.

FIG. 2—INTERIOR OF BLOWER

Therefore, high speed is desirable because it means high efficiency by reason of the low per cent of slippage loss. Blowers not so well made cannot safely be operated at economical speeds.

One element contributing to the serviceability and efficiency of this high pressure blower is the type of gear which is used exclusively. This is the epicycloidal radial flank gear whose tooth curve is generated by a rolling circle the diameter of which is one-half the pitch diameter of the gear. The tooth has minimum curvature and maximum working surface. Its action approaches rolling contact.

Special cutters are used, each designed for only one pitch diameter and one number of teeth. This practice and the fact that the tooth is thickest at the pitch line and can be accurately calipered at both ends, gives a two and three-point working contact as against the one-point contact of ordinary gears. The latter necessarily transmit their power in a series of small impulses or blows at once noisy and destructive. The gears operate in a bath of oil fully protected from dust or injury, being contained in a cast iron housing apart from the blower case. They are supported by bearings on both sides. This construction eliminates vibration, insures correct meshing and a contact the full width of the gear face.

The Latest Improvements in Brinell Hardness Testing Machines

The Scientific Materials Company of Pittsburgh has made extensive studies and numerous practical tests with all existing types of Brinell metal hardness testing machines and has succeeded in developing a much improved model.

The most important drawback in the design of old styles of such apparatus (most of which work on the hydraulic principle) is that the transmission and measurement of pressure is not constant, thus introducing serious errors in the determinations, which increase with the age of the machine. Ground cylinders for pressure transmission can never produce that constancy which is essential in a first-class testing machine.

FIG. 1—SCIMATCO-BRINELL HARDNESS TESTING MACHINE, 3000-KG. CAPACITY, DIRECT-READING FOR DEPTH OF BRINELL INDENTATIONS

FIG. 2—SCIMATCO-BRINELL MICROSCOPE FOR DIAMETER MEASUREMENTS, DIRECT READING

Another important point established in a long series of tests run in the metallographic laboratory of the Scientific Materials Company and confirmed by separate research work along the same lines at the U. S. Bureau of Standards is that the method of determining the hardness of metals by measuring the depth of indentation of the Brinell ball is far more accurate than the method of estimating the hardness from the diameter of such indentations. Furthermore, the depth measurement permits the detection of small differences in hardness and allows the direct reading of the correct result, eliminating all tedious calculations.

The Scientific Materials Company has succeeded in embodying a direct-reading depth gauge in the design of its new Brinell machine and has eliminated the serious errors of old types, by using the only correct

FIG. 3—RELATION BETWEEN PRESSURE AND DEPTH OF INDENTATION ON METALS OF DIFFERENT HARDNESS

FIG. 4—RELATION BETWEEN DIAMETER AND DEPTH OF INDENTATIONS ON ONE BAR OF BESSEMER STEEL, AT VARIOUS PRESSURES

method of hydraulic pressure transmission. As will be understood from Fig. 1, the hydraulic pressure is produced in the bottom vessel of the machine by the turning of a spindle. This permits a steady and finely regulated increase and decrease of the pressure and represents a considerable improvement over the old pumping devices which naturally raise the pressure in jerks.

The hydraulic pressure is then transmitted by a metallic vessel filled with liquid which acts similarly to the closed diaphragm vessel of an aneroid barometer. This is the most accurate and only constant method of hydraulic pressure transmission known to modern science. By this "hydraulic dynamometer" all variations in friction are automatically eliminated. Since there is no friction in the Scimatco machine, there can be no friction variations, and thus the most serious error of the old types of similar machines can never occur in this improved hydraulic press. A very simple and effective controlling device is provided to check and regulate the volume of liquid in the dynamometer vessel, so that this feature is also at all times under full control.

The direct-reading depth gauge carried by the Scimatco-Brinell machine is designed and constructed in such a manner that it will give correct indications to 1/100 of a millimeter, independent of the shape of the test piece. The stage, on which the specimen rests, is automatically levelling so that pieces of irregular shape can be readily investigated. The pressure gauge embodied in the Scimatco machine consists of two separately acting, but self-contained, pressure-measuring units: one is used as "working gauge" in the routine determinations and the other acts as "standard" to check the working gauge from time to time, say, once every month. The connection between these two gauge units and the pressure vessel can be conveniently made and interrupted by spindle valves.

The dial of the gauge is uniformly graduated in equal units, and not in kilograms. A calibration certificate is furnished with each machine, showing the pressure equivalents of these units. The uniformly and finely divided gauge is much easier to read than ordinary pressure gauges which must naturally be unevenly divided, and, in case the calibration of the "working

gauge" should show deviations after a certain time, it will only be necessary to change the calibration certificate.

Should it be necessary to measure the diameter of the indentations, for the purpose of comparing results with those of other investigators who have no means for ascertaining the depth of Brinell indentations, it can be done after the specimen is removed from the machine. For the purpose of very accurate diameter measurement, the Scientific Materials Company has constructed a special measuring microscope (Fig. 2) mounted by universal clamp on a very substantial support and base, permitting convenient diameter measurements on heavy and irregular shaped metal pieces by direct-reading scale.

The eye-piece of this precision instrument carries cross hairs which are focused against the indentation. Then the joint of the cross hairs is set against one side of the indentation, the position of the scale and graduated micrometer screw noted, then moved to the other side of the indentation and the position again carefully noted. The difference between the two positions gives the diameter of the indentation with an accuracy of 1/1000 millimeter.

Figs. 3 and 4, taken from a recent publication of the U. S. Bureau of Standards, will illustrate the superiority of the method of determining hardness by measuring the depth of indentations instead of diameters. Fig. 3 shows plainly that in testing the hardness of soft, medium, and hard metals the depth of indentation at various pressures forms a straight line, thus proving beyond doubt the consistency and accuracy of results.

Fig. 4 shows that on one and the same piece of metal the diameters at different loads are not in proportion, while the depth measurements show a straight line.

Magnetic Clutch-Brake in Rubber Mill

BY C. B. FERGUSON

In the plant of the Boston Woven Hose & Rubber Company it was planned to drive the rubber mills in groups from a single shaft by means of a synchronous motor of 650 hp. The use of a synchronous type motor was desirable because of its characteristic of raising the power factor of the power system. Two problems were presented—one the safety stop feature of every rubber mill, the other the starting of the synchronous motor.

The safety stop feature is an important one in the rubber mill room of to-day. The easy means of throwing off the driving power and applying a powerful brake has saved many hands, arms, and even lives. This feature is provided by the Cutler-Hammer magnetic clutch-brake installed and shown in the illustration Fig. 1.

The starting of the synchronous motor is another problem. With this type of motor means of easy and gradual acceleration of a considerable load must be provided to prevent the load from being thrown on the motor too suddenly and pulling the motor out of step. Since the station supplying power for this synchronous motor was already loaded up to its capacity it was important to provide means of properly accelerating the

FIG. 1—MAGNETIC CLUTCH-BRAKE USED ON MILL DRIVE IN PLANT OF BOSTON WOVEN HOSE & RUBBER CO.

Motor is of synchronous type—650 hp. Arrow points to clutch-brake

motor. This means consisted of the magnetic clutch-brake referred to above.

The equipment consists of a synchronous motor mounted on a common sub-base with a rope sheave, the magnetic clutch-brake furnishing the connection between the motor and the rope sheave. The motor is rated at 650 hp., runs at 240 r.p.m., and under normal conditions carries practically full load when the mill line is operating. Safety switches are installed in the mill room and a slack cable switch in the motor room to stop the motor and line shaft in case of the driving rope breaking.

The chief points of this installation are, therefore, safety in the mill room is provided by safety switches which stop the mills in case of accident; gradual acceleration of the synchronous motor is obtained by means of automatic rheostat and clutch-brake; accidents are prevented because the motor cannot be started by closing one of the safety switches, the station operator must do it by closing the panel switch; the slack cable switch in the motor room automatically disengages the clutch and causes the brake to be applied in case the driving ropes break; a stopping push button is provided on the control panel for ordinary stops when the clutch is simply released but the brakes not applied, thus saving unnecessary wear.

With reference to details of the clutch-brake or clutch-brake accelerator, as sometimes called, it should be noted that the clutch portion consists of a solid circular steel casting, mounted on the driving or motor end of the shaft. This member of the clutch carries embedded in its periphery a single cylindrical magnetizing coil, the terminals of which are brought out to an ordinary pair of slip rings. Mounted concentrically with the coil and the outer periphery, is supplied an adjustable ring of friction so that the metal faces of the driving and driven member do not come directly in contact with each other. This also serves the purpose of providing a permanent air-gap in the magnetic circuit. The other member of the clutch, keyed to the driven or rope pulley side of the shaft consists of a circular steel armature secured to the hub by means of a flat circular spring plate, so that when the magnetizing coil is energized, this circular armature is drawn toward the driving

FIG. 2—SAFETY SWITCH

It is tripped when rod on either side of rolls (running parallel with them) is pulled down. This throws out the clutch and causes brake to be applied instantly.

member of the clutch, the motion along the shaft being accomplished by a slight dishing of the spring plate upon which it is mounted.

It will be noted from the description just given of the clutch portion of this equipment, that this particular form of clutch possesses the advantage of instant disconnection in case of interruption of the magnetizing current and does not require a portion of a revolution for its disengagement. Another feature easily understood from the above description is that with this form of clutch, there is no tendency for it to either release itself or to lock itself due to the mechanical forces exerted as it comes up to speed and while it is running at full speed.

Secured to the hub of the driven member is an ordinary brake pulley, over which there is carried a band brake of the locking type, automatically released by a solenoid mounted on a separate stand in proper relation to the brake beam. The clutch itself is 54 in. in diameter.

Throughout the mill room safety switches (Fig. 2) are installed and these are arranged in series electrically so that the clutch will be disengaged and the brake simultaneously applied, if a safety bar, one of which is provided for each mill, is tripped. In the motor room there is provided a single push button for engaging the clutch, and the clutch is energized by means of an automatic rheostat in such a way as to make it pick up the load gradually and at the same rate of speed for each start.

One novel feature of the electric control system is that if the clutch is disengaged by the operation of any one of the safety stations located throughout the mill, as stated above, the brake is simultaneously applied. If, however, the clutch is disengaged by means of a stopping button on the motor-control panel, the brake is not applied but the load is allowed to coast to rest. Con-

sequently, the quick stop is obtained only in case of an accident.

Another feature of the control system is that when the safety stations have once been tripped, they can be reset immediately, but power cannot be put back on the mill line until the single starting button located on the motor-control panel has been operated. A slack cable switch is also provided so that in case of breakage of the rope drive the clutch is automatically disengaged and the brake applied.

Obituary

James Mapes Dodge, chairman of the Board of the Link-Belt Company and a pioneer in the development of conveying and elevating machinery, died at his home in Philadelphia on Dec. 4, 1915. He was born June 30, 1852, at Waverly, N. J., and received his education at Rutgers College and Cornell University. After a varied experience in the East, partly with shipbuilders, he went to Chicago, where he joined with William D. Ewart,

THE LATE JAMES M. DODGE

inventor of the Ewart link-belt, in the development of the chain business. At that time, about thirty-five years ago, the application of chains to power transmission was exceedingly limited, and their use in elevating and conveying machinery was practically unknown. Later Mr. Dodge came to Philadelphia and formed a partnership with Mr. E. H. Burr, to handle the Ewart chain. Out of this partnership the Link-Belt Engineering Company grew in 1888. In 1889 he developed the conical pile system of storing coal, for which he received the Elliott Cresson gold medal in 1907 from the Franklin Institute. He designed the links and attachments for all of the link-belts now used by the Link-Belt Company.

Fertility of invention and mechanical ingenuity combined with a high order of executive ability were the qualities which brought Mr. Dodge his success. He was for many years closely associated with the late Frederick W. Taylor, in the accomplishment of remarkable results for the benefit of both employers and employees, in a wide circle of industries. His influence was always towards the development of self-help, initiative, ambition, and responsibility in the men, and of a spirit of fair play and humanitarianism as real business assets. Mr. Dodge was a past president of the American Society of Mechanical Engineers, a vice-president of the Franklin Institute, and a member of various other clubs and societies.

Personal

Mr. H. W. Hardinge has been awarded the John Scott medal by the Franklin Institute of Philadelphia for the invention of his conical mill.

Mr. S. A. Ionides of Denver is on a professional trip which will take him through California and the Northwest.

Mr. R. J. Johnston has been appointed superintendent of the Donora zinc smelter of the American Steel & Wire Company.

Mr. W. J. Lakeland of the Burma Mines, Ltd., has arrived in this country from Burma for a visit to the mining and metallurgical centers of the West.

Mr. F. W. McNair, president of the Michigan College of Mines, has been on a trip through the Western States, traveling to the Pacific Coast.

Mr. Benjamin Magnus, formerly general manager for the Mount Morgan Gold Mining Company, Ltd., of Mount Morgan, Queensland, has opened an office as consulting engineer at 61 Broadway, New York City.

Mr. Ernest B. Pearce will have charge of the new tin smelting plant of the American Smelting & Refining Company at Perth Amboy, N. J. Mr. Pearce has had considerable experience in tin smelting in other countries.

Mr. F. Peiter has severed his connection as coke oven engineer with the Gas Machinery Company, Cleveland, Ohio. Mr. Peiter was formerly connected with H. Koppers Company, as designing and constructing engineer, and also with the Tennessee Coal & Iron Company.

Mr. W. R. Rust has resigned the presidency of the company operating the Tacoma smelting plant, which is controlled by the A. S. & R. Co., and will retire from the management of the property.

Mr. W. L. Saunders, president of the Ingersoll-Rand Company and member of the Naval Consulting Board, gave a talk on "Preparedness" at the annual banquet of the Plainfield, N. J., Board of Trade on Dec. 2.

Mr. E. A. Cappelen Smith has been elected a director of the Chile Copper and Chile Exploration companies. Mr. Smith is at present in Chile.

Mr. W. E. Tracy, who for some years past has been superintendent of the mill of the Liberty Bell Company at Telluride, Col., has severed his connection with the company and has gone to Plainfield, N. J.

Book Reviews

Electrothermic Smelting of Iron Ores in Sweden. By A. Stansfield. Bulletin 344, Mines Branch, Department of Mines, Canada. Ottawa: Government Printing Bureau.

This monograph of 67 pages is a most timely publication. It narrates the observations of Professor Stansfield of McGill University (well-known for his valuable book on *The Electric Furnace*), while on a vacation trip in Norway and Sweden in 1914. The data given were accumulated and are discussed with particular reference to Canadian conditions and possibilities.

Interesting points brought out are: The Swedish electric furnaces make charcoal pig iron cheaper than Swedish charcoal blast-furnaces; the thermal efficiency of utilization of the electric energy is 68 to 74 per cent; the system of gas circulation is cumbersome but does not increase the output per kw. year; the cost of making charcoal pig iron in Canada, with power at \$10 per hp. year would be \$20 to \$21 per ton, of coke

iron, \$18.50 to \$19.50. At present, the author sees prospects in Canada only for the electric production of high-grade charcoal pig iron.

* * *

The Sampling and Chemical Analysis of Iron and Steel. By O. Bauer and E. Deiss. Translated by W. T. Hall and R. S. Williams. Octavo, 373 pages, 135 illustrations. Price, \$3.00 net. New York: McGraw-Hill Book Co., Inc.

The translators have rendered a distinct service to their chemical colleagues in translating this fine work. Professor Bauer wrote the 125 pages on sampling, and Mr. Williams translated it; it should be read by every man entrusted with taking samples of iron or steel for analysis. Mr. Deiss wrote the rest of the book, on methods of chemical analysis, including in it only the methods found reliable at the German Royal Testing Bureau, Gross-Lichterfelde, Berlin, and omitting rapid "works methods." The translators have amplified this part by adding about 25 quick methods, mostly of American origin, including also, Walker and Patrick's test for total oxygen. It is a keenly practical book, for the use of expert analysts anxious to get results of high reliability and accuracy.

* * *

The Rare Earth Industry. By Sydney J. Johnstone. Octavo, xii + 136 pages; 42 illustrations. Price \$3.00 (7s. 6d. net). New York: D. Appleton Co.

The principal chapters of the book are on thorium and cerium, titanium, zirconium, tantalum and niobium, tungsten, uranium and vanadium. The contents also include the manufacture of incandescent mantles, pyrophoric alloys and electric incandescent lamps; a final chapter of 18 pages, on "The Industry of Radioactive Substances," was written by A. S. Russell.

The treatment is principally technical and commercial with special emphasis on statistics of production and cost. Each chapter gives, regarding the rare element, a fairly complete bibliography, its occurrence, production, treatment, uses and methods of analysis. The field covered is so extensive and varied that the author could not have first-hand information on every topic, as a necessary consequence some of the statements (e.g. on pyrophoric alloys) are not as reliable as are those drawn directly from Mr. Johnstone's experience. But in the line of the mantle industry and the manufacture of electric lamp filaments the descriptions of commercial practice are particularly complete and satisfactory. Mr. Russell's chapter on Radioactive Substances is also cleverly written. The book, as a whole, contains an unusual amount of scarce information.

* * *

Chemical Constitution and Physiological Action. By Prof. Dr. Leopold Spiegel. Translated from the German by C. Luedeking and A. C. Bolston. 12mo, 156 pages. Price, \$1.25. New York: D. Van Nostrand Co.

This is a serious attempt to collate what is known of the relations between chemical constitution and physiological action, in order to provide a basis for rational scientific medical treatment. After a chapter of general considerations, in which the subject is discussed from a very broad point of view, there are 20 pages given to the consideration of various inorganic compounds and the rest of the book to organic—20 pages to the aliphatic series, 17 pages to the aromatic series, and 70 pages to nitrogen compounds. The odor and taste of these medicines are not considered, but only their medical effects as related to their chemical structure. The work was well worth translating for the benefit of medical students and progressive practitioners.

Industrial Conditions After the War

A rare, a magnificent, opportunity is afforded students of political economy, to answer the great question, what will be the economic and financial conditions in the countries of the world after the war. It is a problem to which many are addressing themselves. Our captains of industry have been addressing themselves to it, not with the cocksureness of the type of political economist with which we are all more or less familiar, but rather in the mood of sounding a note of warning. That, in particular, was the attitude of Chairman Gary of the United States Steel Corporation when, apropos of nothing in particular but the conditions and possibilities as he saw them, he gave a long statement to the public on Jan. 8. He does not attempt to solve the problem, but he points out that there are grave possibilities awaiting us, and emphasizes the point that present industrial conditions are absolutely no criterion as to conditions that will prevail after the war.

It is an interesting fact that in nearly all of the many utterances on "After the war—What?" there is a strong appeal that the Government should raise a wall against "dumping." The unanimity and pointedness of the proposal, coming from so many quarters, suggests not so much certainty of thought as uncertainty, in that an anti-dumping arrangement must prove advantageous in one set of conditions, and cannot be harmful should a diametrically opposite set of conditions prevail. It is not necessary, in other words, to prove that the remedy is needed in order to advocate that it be provided. The conclusion can be reached without arranging in advance one single set of arguments leading up to it.

It is elementary, in the dealings between nations, that if one finds itself with more money or credit than others, it tends to spend the preponderance with the others. The war is rapidly increasing our preponderance. Apparently there are many who go no farther than to assume that the adjustment will be in merchandise. Others, who recognize that adjustment can also be made by the flow of capital instead of merchandise, express grave fears that such a flow of capital out of the country will be injurious. In the economic history of the United States the merchandise trade balance was almost invariably against us until 1876, and thereafter, until 1898, the favorable balances were relatively small. For a part of the time the American merchant marine earned some money, to that extent offsetting merchandise imports. During much of the time capital was flowing into the country, and in recent years it has been necessary for us to pay annually hundreds of millions of dollars return upon this capital. This has been done by our exporting more mer-

chandise than we imported. We have prospered with the borrowed money, and have been well able to pay for its use.

In the normal development of any nation such as ours there should be such a period of borrowing, for development purposes, but it seems natural that there should be a time limit to this period. The tenant should not always be a tenant, sending a portion of the fruits annually to the lord of the manor. The war tends to change our position from that of a borrowing to that of a lending nation. The real question is whether the time is ripe for such a change, whether our internal development has proceeded far enough that we do not need the extra capital that has come and is still coming to us.

Political economists recognize a factor known as "the disinclination of capital to emigrate." It is difficult even when all the conditions are known to set a value for the factor, but it exists. The capital will not be drawn from this country unless better returns are promised abroad, and that brings us in substance to the important question what will be the value of goods in different countries. Of course, many other important matters enter, but the flow of merchandise, subject to tariffs, either straight or anti-dumping, hinges upon their relative values. Relatively low-commodity values in foreign countries will exert two influences, to move the commodities to this country, and to disincline our capital to move to those countries. In the event of commodities abroad proving to be cheap, and of their importation being retarded by tariffs, our capital will tend to remain with us. Then, however, comes the more serious question what we shall do with the capital, whether we shall invest it wisely or spend it riotously. Can we spare capital, in view of our own development needs, but if we do retain it shall we use it wisely?

Science and Engineering

Dr. John A. Brashear's charming and sympathetic personality is finely displayed in his presidential address presented before the American Society of Mechanical Engineers last month. He spoke of engineering achievements of centuries long ago—of the pyramid of Cheops and the via Appia which was in perfect repair nearly six hundred years after it was finished. "I have always had the conviction that we give too little thought to the pioneers in any line of research and I have often bowed my head in reverence to those who, with the most limited means and equipment, by patient, persistent plodding, wrested the secrets of nature from their entanglement."

But the principal subject of Dr. Brashear's address was the relation between science and engineering. "Where shall we draw the line between pure and applied science? For myself, I have been unable to find aught but a hazy line of demarkation." When the velocity of the propagation of light waves was determined by scientific reasoning and experimentation of the most refined nature, the process of solving the problem remained for a long time in the domain of the exact sciences as a masterpiece of the human mind. "But who

dreamed to what utilitarian purpose these light waves would be made subservient? The genius of a Michelson carried them into the workshop, thence to the International Bureau of Weights and Measures at Sevres, and gave us a value for the international meter in terms of light waves that will remain absolutely unalterable as long as this old world moves in the lumeniferous ether of the universe." "Getting nearer the utilitarian service of the scientific study of light waves, Dr. Anderson of Johns Hopkins has utilized them in making screws of hitherto unheard-of accuracy." And when in railway shops nuts made by some firms would not screw on bolts made by others, the problem at first baffled the ability of the most prominent manufacturers of tools of precision in the country, but it was solved through the co-operation of a professor of astronomy. And the development of instruments for mechanical measurements to the highest state of precision has been a mighty factor in the development of interchangeable machinery.

And this utilitarian use of science in making possible the construction of accurate screws has again reacted, as it were, and enabled the scientific mechanic to produce a little optical device that rivals, if it does not surpass, the telescope—the diffraction grating. "On the plane surface of its polished plate, made accurate to one-tenth of a light wave, or within one forty-five thousandths of an inch, are ruled more than 45,000 lines between which there is no greater error than one two-millionths of an inch. With this delicate piece of apparatus, made possible first by rigorous scientific research, second by the skill of the artisan, third by a knowledge of and vigorous care to avoid temperature changes, and fourth by the accuracy of the mechanism which includes the accurate screw mentioned above, the astro-physicist has been able to tell us the composition, temperature, and distance of the stars. It is also possible for the physicist, the chemist, to tell us the purity of the material he is called to investigate; indeed, it makes itself subservient to many phases of engineering in the domain of metallurgy. And the end is not yet. Where can we draw a sharp line of demarkation between pure science and its relation to any and every form of engineering?"

Hydrolysis of Alkali Cyanide Solutions

It occasionally happens that some of the refinements in a metallurgical process are deferred for study until long after the essential features have been made commercially successful. This may be because the refinements were not early appreciated, or because they are not forced on the attention through economic necessity. In the course of time, however, incidents arise which direct attention to points that have escaped critical thought.

A case in point seems to be the recent study that has been given to the part played by hydrolysis in the consumption of cyanide in the treatment of gold ores. It has long been known, of course, that the apparent requirement of cyanide was far in excess of that indicated

by the dissolution of the precious metals. Previous study also has been given to cyanicides of various kinds, and means have been devised to minimize their effect. Nevertheless, when all the recognized causes of cyanide consumption have been considered, we are still confronted with the fact that a large item of loss remains unaccounted for. The suggestion is now made that this loss is due to hydrolysis of the alkali cyanide into caustic alkali and hydrocyanic acid, and the volatilization of the latter from the solution.

In our synopsis of current literature in this issue we give abstracts of two important papers bearing on this subject, by H. A. White and H. M. Leslie of South Africa. In our issue for Dec. 15, we reviewed Mr. Leslie's United States patents for a system of cyaniding designed to obviate the loss due to hydrolysis. All of these are deserving of the careful consideration of cyanide metallurgists. If, as Mr. Leslie believes, a loss of from 30 to 50 per cent of the cyanide used is to be ascribed to hydrolysis, and a substantial portion of this loss can be prevented, the subject is of vital importance. South Africa consumes roughly 5000 tons of cyanide per annum; the United States, 2500 tons; Canada, 1200 tons. Mexico is an uncertain quantity, but in normal times would show a large consumption. Even a small percentage saving on this combined tonnage would be an important item of economy. We invite discussion of the subject.

English in Mining Schools and Universities

The impression grows that English should constitute almost a major course in the curricula of our schools of mines. One has but to read examination papers, theses, and even business letters written by undergraduate mining students to be convinced of this need. That there is a lack of proper preparatory work in high schools there is no doubt; but the college cannot take refuge in this excuse and escape its duty to those who are graduated with baccalaureate or professional degrees, presumably as men of some cultural attainment as well as technical knowledge.

Among students there is a strange antipathy to the study of English as something non-essential and of trifling importance. This, however, makes it more imperative for the college faculty to prescribe what is best. Perhaps it points also to a need of presenting the subject in a manner appropriate to technical students, so that they will appreciate its importance and cease to regard it as a side issue of no consequence.

It should not be difficult to impress the student with the fact that his written work is his personal representative and often the sole medium by which he is judged; that the written or printed word is subject to closer scrutiny and more critical analysis than speech; and that glaring errors in composition and spelling stand out so prominently as to distract the attention of the critical reader. It is not necessary that the engineer acquire a brilliant style or fanciful diction, but his writing should be characterized by simple, precise, and logical expression.

There is a curious inconsistency in this failure of the student to appreciate the value of English. Whereas an engineer practices exact science, using instruments of accuracy and precision, he has strangely overlooked the necessity of familiarizing himself with the equally exact, precise, and accurate tools of expression. Further, as a professional man, the engineer is expected to embody culture as well as technology, and the least he can do in adorning the latter with the former is to have a good working knowledge of English.

Several years ago an official of a large company took the trouble to investigate the training and ability of a number of engineers by examining critically three hundred of their reports on mining properties. Among graduates from technical schools only, he discovered almost unbelievable ignorance of the principles of English composition; and it was only in the work of those men whose engineering training had followed a liberal arts or classical education that culture and refinement were shown in the correct use of our language. In commenting on this striking discovery, the investigator said: "If clear writing is necessarily preceded by clear thinking, then a large body of technically trained men is hopelessly lost in the fog."

We are aware that the teaching of English has been receiving more attention in mining schools during the last few years; but there is still room for improvement. The subject must receive special attention; it cannot be handled satisfactorily by the other instructors, although they can be of benefit in supporting the special work. We can imagine that difficulty arises in finding time and place for the course in a crowded curriculum, but this will have to be done until students come to college with better training. Two alternative solutions are to lengthen the course of study or make mining engineering a post-graduate course, both of which seem of doubtful propriety at the present time.

Yet it would be unfair to speak of this problem as though it concerned mining schools alone. As a matter of fact it apparently concerns with few exceptions all our higher institutions of learning. No less a competent and well-informed observer from the engineering field than Mr. Arthur D. Little, made the following pointed remarks the other day in the symposium on the university and the industry before the New York Section of the American Chemical Society (page 941 of our issue of Dec. 15, 1915): "The business man seldom has at his disposal any more potentially efficient tool than the English language, but in his hands it is a tool which is often rusty and very seldom so keen and highly tempered as to be capable of rendering its highest service. The fault of this is largely with our universities, and the remedy, so far at least as their own students are concerned, is in their hands. Our great institutions of learning are every day disgraced by the inability of their recent graduates to make a concise and convincing oral statement of a series of facts, to prepare a well-organized and adequate report, or even to write a graceful and informing letter."

Reader's Views and Comments

A Board that Receives No Pay and Provides for All Its Own Expenses

To the Editor of Metallurgical & Chemical Engineering:

SIR:—In spite of the extraordinary extent of the field now covered by governmental activities, intelligent people still remember at times that a fundamental function of a government is to provide means for repelling foreign aggression. While immense amounts of the taxpayers' money are now spent in paying employees by whose activities many citizens are benefited but remotely or not at all, we are all vitally interested in the defense of our lives and property.

With this in mind, the following statement of Dr. L. H. Baekeland (METALLURGICAL & CHEMICAL ENGINEERING, Dec. 15, 1915, page 944) is almost incredible:

"No member of the Naval Consulting Board draws any salary nor gets any remuneration from the Government.

"We all pay our traveling and hotel expenses and each member feels that if he can give his time, free of charge, to the Government, he can still better afford to pay his own expenses.

"This program is carried out so scrupulously that even the cash for the purchase of stationery and printing is furnished by members of the board, who are monthly assessed among themselves."

It is surely bad enough that the politicians whom we allow to govern us should take our money for all sorts of unnecessary expenditures without putting us to shame by letting a group of scientific men pay for the privilege of working for our defense.

FRANCIS A. J. FITZ GERALD.

Niagara Falls, N. Y.

Two Instructive Accidents from Chemical Engineering Practice

To the Editor of Metallurgical & Chemical Engineering:

SIR:—The two accidents described in the following notes may be of interest to your readers. They have occurred under my observation.

A MISAPPREHENSION AS TO THE EFFECT OF CHANGING THE CENTER OF GRAVITY

A few months ago, at one of the largest chemical manufacturing concerns in the country, a peculiar accident occurred, illustrating the result of not taking into account the shifting of the center of gravity in a cylindrical vessel standing at an angle with the horizontal, while being emptied of a liquid.

In this case, a standard-gage railroad tank car, loaded with acid, was being placed upon a car float preparatory to being ferried across a stream about 1 mile wide. The tide being out, the float was several feet below the level of the tracks, and the hinged "bridge" which formed the connection from land to float stood at a considerable down-grade. As the car was being handled

over this bridge, the knuckle pin of the coupler broke and the car ran away (the brakes not holding on the steep grade) and passed upon the car float, traversed its entire length, crashed through the 12-in. x 12-in. buffer timber at the end of the track, demolished the float captain's cabin and only came to rest when one of its trucks was overboard in 12 ft. of water, and with one end of the tank projecting over the end of the float.

Those in attendance discussed the possibility of the tank dropping into the water, but reasoned that since it had come to rest, if the remaining truck were securely lashed to the end of the car still on the float, it would provide counterweight sufficient to make the tank stable enough to permit the float being moved to an adjoining wharf where provision in the way of storage tanks and compressed air were available for unloading the acid from the car. This shift was made, and the unloading progressed without incident until the liquid reached a level indicated by the dotted line in Fig. 1, when, without warning, the tank suddenly tilted over the end of the float, landing end-down in 20 ft. of water, and taking the truck along with it.

Fortunately no one was injured during the affair, and after a derrick was procured, the unloading was continued by making additional holes in the end of the tank (which projected above the water) for the application of compressed air and acid piping. The tank and trucks were recovered. Only a slight amount of acid was lost.

MISJUDGING THE CAPACITY OF A CRANE

A few months ago the writer was engaged in the installation of an iron ore concentrating machine, and among other appliances had a locomotive crane whose capacity, or overturning moment, was rated by the builders at 150 ft.-tons.

One section of the apparatus weighed 6 tons, and the nearest point we could get with the crane called for a radius of lift of 24 ft., or what would amount to an overturning moment of 144 ft.-tons. As the casting in question was loaded on a flat car, we placed the crane as near as possible to the point it would occupy when landing the casting and placed the flat car back of it, so that all we would have to do would be to raise the casting from the car, swing the crane through an arc of about 180 deg., move slightly ahead, and land the casting. The crane being fitted with rail clamps, we adjusted these but did not think it worth while to place out-riggers under the frame, as the load was within the specifications.

However, much to our surprise—and regret—when the crane had swung about 90 deg., it suddenly turned over, dropping its load, which narrowly missed two workmen. Fortunately no one was injured except the craneman, who suffered a sprained ankle after jumping to the ground, and tripping on an obstruction while running to a point of safety.

FIG. 1—ACID TRANSFER

A—Tank; B—Truck remaining on car float; C—Car float; D—Bridge; E—Wharf level

In pondering over the mishap, it suddenly occurred to us that the crane was standing on a sharp curve—22 deg.—was swinging the load toward the center of this curve and the super-elevation of the outer rail was sufficient to shift the center of gravity from the track center toward the inner rail, thus reducing the overturning moment on that side an amount sufficient to tip the crane over.

A serious oversight in the construction of this crane was brought out in this accident, this being that the boiler was not anchored to the frame, with the result that when the crane tipped, the boiler shifted badly breaking the 2½-in. steam pipe near the boiler, and the escaping steam would undoubtedly have scalded the operator had he not been nimble enough to avoid being caught between the boiler and the levers. All owners and users of these cranes, whether engaged in bucket or actual crane service, should have this point examined at once, and suitable anchorage provided for the boilers should it be found lacking, as a capsizement is liable to occur at any time, and the results may not be as fortunate as was the case in the accident above mentioned.

Low Moor, Va.

J. W. RUPERT.

Carrie Jane Everson and the Flotation Process

BY H. C. PARMELEE

When the process of concentration by flotation came into prominence in the United States several years ago the name of a woman, Carrie J. Everson, became generally known to engineers through her early contribution to that art which is now so widely practised. This remarkable woman had twice patented her ideas on flotation: first as a resident of Chicago (348,157, Aug. 4, 1886), and later from Denver (471,174, March 22, 1892). The latter patent was issued jointly to Charles B. Hebron and Carrie J. Everson.

The fact that Mrs. Everson was once a resident of Denver aroused among the engineers of that city a special interest in her identity and whereabouts. The matter was frequently a subject of casual conversation, and the suggestion was often made that a systematic search should be undertaken to ascertain whether the woman were still alive, and if so, to learn more concerning her work and the incidents that led to her discovery. The latter point was of particular moment, since a legendary account credited "Miss Everson, a Denver school teacher," with discovering the phenomena of flotation "while washing greasy ore sacks in her brother's assay office in Denver." Since no member of the mining and metallurgical fraternity in Denver could recall an assayer by the name of Everson, this story was open to doubt and offered no probable clue to the truth.

In any event, no serious effort was made to ascertain the facts until, in July, 1915, the Colorado Scientific Society appointed a committee for that purpose, consisting of George E. Collins, Phillip Argall and Howard C. Parmelee. The society's object was twofold: first, to determine beyond question the woman's part in the patented discovery, and second, to consider the advisability of proposing some form of memorial in her honor. One of the first results of the committee's work was the discovery that Mrs. Everson died at San Anselmo, Cal., Nov. 3, 1914, a fact that caused keen regret that the society's search was not undertaken at an earlier date, when the results might have been of more than historical value, not only as relating to Mrs. Everson, but also to the metallurgical industry. It can be imagined, for instance, what intense interest would have been aroused by her appearance as a witness in the hotly contested suits over the validity of certain flotation patents, for Mrs. Everson

was still alive and active during the time of the litigation between Minerals Separation, Ltd., and the Butte & Superior Copper Co. And it may be more than idle speculation to consider what might have been the effect of her testimony in establishing the prior state of the art as disclosed in her own patents.

Investigation by the Colorado Scientific Society

The society's committee began its investigation by endeavoring to locate the witnesses to the Denver patent, and one Thomas F. Criley, who was credited with an early attempt to introduce the process at Baker City, Ore. As a result of searching the Denver city directories for 1885 to 1915, inclusive, one of the patent witnesses was found, Mr. E. A. Fay, in whose family Mrs. Everson had at one time lived. Many interesting details were disclosed in this directory search, among which was an inconspicuous item in 1891, "Hebron-Everson Process, Room 22, 1452 Lawrence St.," which was eloquent of the hopes and ambitions of the early promoters.

From Mr. and Mrs. Fay we ascertained many interesting facts regarding Mrs. Everson, and particularly that she had removed to California about 1909, where her son, John L. Everson, was supposed to be living. While this clue was being followed the writer had what he supposed was only a casual conversation with Mr. Arthur Chapman, a special writer for the *Denver Times*, giving him the story of the Everson matter as far as it had been developed. With true newspaperman's instinct, Mr. Chapman scented a good story and prepared an elaborate article for his paper. Among other features he emphasized the fact that Mrs. Everson's present whereabouts were unknown. The story immediately attracted attention throughout the West, and as a result of it we received a number of letters from Mrs. Everson's former acquaintances, giving various bits of information. Among others came a letter from Miss Anna E. Watson, of Pueblo, Col., who had formerly worked with Mrs. Everson as a nurse in Denver, advising us that Mrs. Everson's last known address was San Anselmo, Cal. At the same time the *Rocky Mountain News* located John L. Everson at the same address. Mr. Everson was immediately communicated with and has given us practically all the information available regarding his mother's work. The following notes are based on his correspondence.

Biographical Sketch

Carrie Jane Billings was born at or near Sharon, Mass., about Aug. 27, 1842, of early Pilgrim ancestry. About 1851 she removed with her parents to Springfield, Ill., where she received her early education, "the best possible at that period." On Oct. 3, 1864, she was married to William Knight Everson, a Chicago physician. Five children were born, of whom the only survivor is the son mentioned above. Dr. Everson was very successful in his medical practice, and Mrs. Everson took a deep interest in his work, studying various branches of science and becoming proficient in chemistry.

About 1878 Dr. Everson became interested in mining ventures, and is reported to have invested \$40,000 in the Golden Age Mining Co., of Brick Pomeroy fame. This echo of the past will recall to some who are familiar with the early history of mining in Colorado other incidents in the career of that illustrious promoter, Brick Pomeroy. Dr. Everson soon realized that his investment was ill-advised, and he abandoned his interest in it. Mrs. Everson, however, is reported to have hoped that something might be saved from the wreck, and began the study of mineralogy in order to

fit her for technical investigations. Her son states that he can distinctly remember seeing her work in the laboratory, grinding ore with mortar and pestle and submitting the powder to microscopical examination, using Dr. Everson's instruments.

Some time in 1879-1880 Dr. Everson took a trip to Mexico, possibly for his health, since it is known that his health failed about that time. During this absence Mrs. Everson discovered what she then termed the "chemical affinity of oils and fatty substances for mineral particles." Her method of demonstration is disclosed in the Chicago patent, reference to which has already been made in this journal. On Dr. Everson's return from Mexico the two engaged in research for the purpose of perfecting Mrs. Everson's discovery. Dr. Everson abandoned his medical practice and devoted his resources to the work, with the result that the patent was finally obtained. Efforts were made to interest mining men in the process, but with little success, and the Eversons' financial resources gradually ebbed. Finally, on Jan. 20, 1889, Dr. Everson died at Denver, and his wife was left to care for herself and young son. As a means of livelihood she took up obstetrical nursing and practised this profession for many years in Denver.

At this juncture she made the acquaintance of Thomas F. Criley, who became interested in the process. He and John L. Everson went to Silver Cliff, Col., and secured the

use of an abandoned, dilapidated ten-stamp mill for experimental purposes. An 800-gal. tank was constructed, with revolving paddles and an adjustable horizontal partition. The partition was made of two pieces, hinged in the middle so that the leaves could hang vertical or be raised to a horizontal position. In carrying out the test, the tank was filled with water, and after the ground ore and oil were thoroughly mixed the mass was placed in the tank. The paddles were revolved so as to agitate the mixture, and after thorough agitation the dividing partition was raised to separate the floating mineral and oil from the water and tailing. The latter was removed through a gate in the bottom of the tank. The oily concentrate was collected in iron pans and placed in the fire-box of the boiler in order to burn off the oil. Mr. Everson reports that the ore thus treated was quite coarse, over half of it larger than 40 mesh. The concentration ratio was about 4:1, but for one reason or another the general result was not successful. Mr. Criley then tried to interest people in Baker City, Ore., and Mrs. Everson went there with him for that purpose, but was not successful.

Introduction of Hebron-Everson Process

The advent of Charles B. Hebron on the scene occurred about 1891. He is reported to have been a chemist from New York, claiming to have had experience in ore concentration. It appears that he

had little faith in the use of oil, but when Mrs. Everson explained that she had also made use of lamp-black and other materials to effect flotation he showed more interest. Through his instrumentality funds were secured for getting the second, or Denver, patent, which discloses the use of "charcoal, coke, lamp-black, plumbago, any sort of friable vegetable fibers—such as bark, moss, straw, cotton, wool—also sulphur (sublimed), aluminum trihydrate, hydrated lime sulphate, sodium oleate and other cheap salts of sodium, also the cheap metallic sulphates and oleates" as "buoyant materials."

Mr. Hebron secured funds for experimental work and gained the co-operation of a Mr. Pischel, of Denver, in consideration of an interest in the patent. They carried on some work in an old building in Valverde, near Denver, where Hebron set up a sluice box about 60 ft. long, 6 ft. wide and 18 in. deep. Cleats were nailed on the bottom of the box at intervals of 2 ft. to produce gentle ripples on the surface of the water running through the box. An adjustable

gate at the lower end of the sluice permitted regulation of the surface disturbance due to the cleats. The mixed ore and buoyant material was gently sifted onto the surface of the water at the head of the box, and by the time it had reached the lower end the separation of mineral and gangue was complete and the two products could be

CARRIE J. EVERSON

Photograph taken shortly after her marriage in 1864

CARRIE J. EVERSON

Photograph taken when she was a nurse in Denver

collected separately.

After a few tests the process seemed to be successful, and the principals were elated at the prospect. Here, however, another touch of human nature entered into the misfortunes of the Everson process, for "Mr. Hebron and Mr. Pischel quarreled over the millions each was to make, and the whole matter was abandoned."

As far as we are able to learn, the succession of disheartening failures now caused Mrs. Everson to abandon hope of ever bringing the process to a successful issue, and she took no further active steps in that direction. In 1892 she accepted a position as visiting nurse for the Denver Flower Mission and continued in that position until 1906. At that time she was engaged on the staff of the State Industrial School for Girls, near Morrison, Col., and remained there until she removed to California in 1909. She died at San Anselmo, Nov. 3, 1914, and was buried in Mount Tamalpais Cemetery.

Inventor's Confidence Unshaken

Although Mrs. Everson apparently abandoned all hope of ever commercializing her inventions, she is reported to have been confident that some one would at some time do so. She did not learn of the success of flotation until after her patents had expired, and at that time it was too late for her to secure any advantage. Her son states that she always felt that

a combination of flotation and cyanidation would prove profitable—a prophecy that is about to be fulfilled.

In personality Mrs. Everson is described by her friends as a quiet, kindly, self-sacrificing woman who devoted her life to those less favored than the majority. All who knew her bear testimony to her sterling character and worth and her happiness in being of service to others.

The accompanying photographs show her first as a young woman, shortly after her marriage, and later as a nurse. The former was furnished by her son, and the latter by Mr. Fay. As far as we are aware, these are the only photographs extant. Mr. Everson states that his cottage at San Anselmo was destroyed by fire in December, 1910, at which time all of Mrs. Everson's patent papers, contracts and correspondence were destroyed. Enough facts have been established, however, to set at rest the rumors, legends and apocryphal stories regarding her life and work.

The question has been asked repeatedly, Why was not Mrs. Everson's work appreciated in an earlier day before the patents expired? For answer there may be several reasons. In the first place we may imagine that the process was ahead of its time as far as metallurgical necessity was concerned, and therefore was not appreciated. Again, we may easily conceive that it was passed by as "a crazy notion" that did not appeal to the practical men of the time. And finally, with all due respect to its inventor, we can readily believe that there were some who scoffed at the process because it was "discovered by a woman." On the other hand, there may be found a reason in the fact that the second patent departed from the fundamental ideas of the first, viz., the use of oil and fatty substances, and substituted lamp-black and a long list of other buoyant materials. In other words, the Hebron-Everson patent does not now seem to be as important as the original Everson patent, and it may have been a mistake to admit the innovations insisted upon by Hebron, even though they were first conceived by Mrs. Everson. However, the fact remains that Mrs. Everson stands in the position of an originator of the process of concentrating mineral by oil flotation, and while no financial advantage accrued to her from her discovery, she is generally credited with having disclosed in 1886 all the essential elements of the process as practised to-day.

The Iron and Steel Market

The slight lull that seemed to develop in the steel market in the second half of December proves to have been of no significance. In so far as it represented a holiday slackening its influence disappeared before the normal time, for the characteristic holiday lull is supposed to extend to the middle of January at least, an evidence of the holiday influence being quickly shaken off appearing in the fact that several important advances in finished steel prices occurred the first week in January. In major part, however, such quieting down in steel buying as occurred was due to the fact that the market was fully sold, indeed oversold. The mills cannot indefinitely continue to sell week by week much more material than they produce, nor can buyers indefinitely buy in such manner.

In the case of nearly all steel interests the December bookings of actual shipping orders made a new high record, the bookings being chiefly in the form of specifications against contracts, and chiefly contracts written long ago. Sometimes the passage from one calendar quarter to another effects a decided change in the rate of specifying, the contracts coming into force being at materially higher prices than those just expired. In

this case, however, steel price advances have been so rapid that the current market is much higher than the level at which many contracts for the present quarter were written, and specifications this month are likely to prove very large, possibly as large as in December. Taking the mills as a whole it will not be until the second quarter of the year that they will be given much opportunity to catch up in their rolling schedules, while the outlook is that they will never catch up until consumption decreases.

Since early in December shipments of steel from the mills for direct export have been greatly curtailed, chiefly through the action of the railroads in placing embargoes until the large volume of material in cars at eastern terminals has been moved. The net effect of the embargoes has been reduced, but only slightly, in the past fortnight. During this curtailment in export shipments from mills the shipments to domestic buyers are correspondingly increased, and the material is all welcome. A still greater scarcity of steel in the domestic market is to be expected when export shipments are increased.

Chairman Gary of the United States Steel Corporation on Jan. 8 made a lengthy statement to the public, through the medium of the daily press, expressing the belief that there was great expansion and the fear that there was also great inflation. He pointed out that prosperous conditions were assured only while the war lasted, there being grave dangers thereafter, and stated that he expected the war to end sooner than most people expected. As to steel prices, they were high, but the buyers frequently caused advances themselves, and steel price advances were probably not ended.

During the first week in January the following advances in steel prices occurred: Bars, plates and shapes, \$1 a ton; standard steel pipe, line pipe and oil country goods, \$1 to \$2 a ton; steel boiler tubes, \$4 a ton; blue annealed sheets, \$3 a ton; railroad and small spikes, \$3 a ton; cold roll strip steel, \$5 a ton; rivets, \$2 a ton, and bolts and nuts, 10 per cent.

Steel ingots are being produced at the rate of 40,000,000 or 41,000,000 tons a year, and the new construction of open-hearth steel furnaces, including two cases of duplexing plants, involves an addition of between 10 and 11 per cent to the capacity. More than half the new construction will likely be completed by July 1. There appears to be new construction in finishing departments sufficient to prevent a surplus of unfinished steel. Ten blast furnaces are being built or are definitely projected, representing about one-half the raw material requirements of the additional open-hearth capacity. As pig iron has already become scarce, and both pig and scrap prices have advanced sharply in the past two months, there are possibilities that the alignment of the new construction program now being worked out will produce a definite shortage of pig iron.

The steel mills are now booking very little business in the form of open contracts for specification in future. Specific orders they will accept for such delivery as they can compass. The total of specific and contract commitments represents an average of fully six months of full production, but in some lines the commitments are much greater than in others, being greatest in rails and large steel rounds, rolled alike on rail mills, in plates and in bars, and smallest in tubular goods and wire products, which are customarily not sold far ahead. The volume of wire business on books is unprecedentedly large for the product.

The United States Steel Corporation's unfilled obligations at the close of December were reported on Jan. 10 to have been 7,805,220 tons, representing an increase of 615,731 tons during the month. The normal rated capacity for the month, in steel products for sale,

may be taken at 1,220,000 tons, so that the increase in unfilled obligations during the month was fully 50 per cent of the capacity, while the shipments were slightly in excess of rated capacity, making the bookings more than 150 per cent of the capacity. A large part of the increase in obligations, however, was doubtless in tin plate, which is sold under contract for the entire season of 1916.

Pig Iron

Pig iron has been quiet since the first of the month, as to the actual turnover, but the market is fundamentally very strong, and the sharp advances during December, averaging fully \$1.50 per ton, do not seem to have left the market top heavy in any sense. The furnaces are well sold up for many months and shipments are readily taken. The market is quotable as follows: No. 2 foundry iron, delivered Philadelphia, \$19.75 to \$20.25; f.o.b. furnace, Buffalo, \$18 to \$18.50; delivered Cleveland, \$18.80; f.o.b. furnace, Chicago, \$18.50; f.o.b. Birmingham, \$15 to \$15.50; f.o.b. valley furnaces, 95c. higher delivered Pittsburgh. Bessemer, \$21 to \$21.50; basic, malleable and forge, \$18 to \$18.50; No. 2 foundry, \$18.50 to \$19. Several foreign producers of ferromanganese have withdrawn their contract quotation of \$110, Baltimore.

Steel

The market for soft steel billets continues to be very narrow, as the regular consumers are fairly well covered by contracts, at much lower than present asking prices, about \$32 to \$33 for Bessemer and \$35 for open-hearth, and in view of prices obtainable for finished products it is only occasionally that a buyer could afford to pay the prices asked. Sheet bars are nominally quoted at the same level as billets, with consumers covered by contracts. Ordinary forging billets are scarcely quotable, but forging or rolling billets to conform to war steel specifications are bringing \$50 or more. Rods are probably within the range of \$40 to \$44, Pittsburgh.

Baltimore Meeting of the American Institute of Chemical Engineers

Inclement weather spoiled slightly the excursions on the first afternoon of the Baltimore meeting (the eighth annual meeting) of the American Institute of Chemical Engineers. But it could not detract from the success as a whole. There was an unusually good attendance at the first session, held on the morning of Wednesday, Jan. 12, at the Hotel Emerson, some 60 or 70 members and guests being present. Sickiness, unfortunately, prevented the president, Dr. George D. Rosengarten, from being in the chair. In his stead Past President Dr. Samuel P. Sadtler of Philadelphia acted as chairman.

A cordial welcome was extended to the Institute by the Deputy Comptroller of Baltimore and the reply was made by Professor Withrow, who emphasized that the city of Baltimore had always been a center of chemical activity. The annual reports of the officers, the council, and the different committees were presented, which showed the institute to be in good financial condition and quite active through its various committees.

The professional session which followed brought two very interesting papers. The various factors which affect and influence the development of the chemical coal-products industries in this country were discussed by Mr. H. W. Jordan of the Semet-Solvay Co., with great lucidity and often with a fine, quiet humor. Dr. W. F. Rittman of the Bureau of Mines followed with a discussion of the chemical engineering problems of

the cracking of petroleum, speaking with characteristic directness and impressiveness.

Mr. Jordan showed convincingly that if the United States is to have a complete industry in the manufacture of the many different products derived from coal, the following essential conditions must be fulfilled: co-operation of the American acid and alkali manufacturers with the coal-tar industry; co-operation of the American consumers with the American producers through long-term contracts to assure the American market; establishment of the industry on a peace-scale big enough to make it a fundamental factor in national defence; establishment on a profitable commercial basis of the manufacture of nitric acid, by fixation of atmospheric nitrogen; nationalization or rather internationalization of the industry to insure a balanced world market for all by-products; development of a system of twentieth century common school and technical school education, and maintenance of a rational tariff.

The paper was discussed by Messrs. Frerichs, Withrow, and Prochazka who gave reminiscences of early American achievements in the chemical coal-products industry.

Dr. Rittman, in his paper on the cracking of petroleum, said that the variables in the cracking reactions are temperature, pressure, time, concentration (mass action) and contact surface (catalysis) and that the engineering apparatus must be designed to fit these variables. The source of the oil is not of primary importance, but the desired end products are. Dr. Rittman dealt successively with the production of gas, of gasoline, and aromatic hydrocarbons, discussing in each case demand, supply, and future. Pictures and lantern slides were shown of the bureau's "Plant No. 1," in Pittsburgh, which produces 500 gal. benzol and 500 gal. toluol per day. Plant No. 2 which was started last week very successfully, seems a great improvement. Six or seven other plants are being erected or projected.

In the discussion Dr. Cushman and Dr. Frerichs asked some questions which were answered by Dr. Rittman.

At the Wednesday evening session the first paper was read by Dr. A. D. Little of Boston. This was a brilliant discussion on wood waste utilization, showing that the potential profits in utilizing this waste would be much greater than the actual profits in the present industry. When this waste is used as raw material an enormous by-product industry can be formed. The technical staff of Dr. Little's organization made a careful investigation of this problem on a large scale, over a period of eight months. They found that with a cut of fifteen billion feet of yellow pine the Southern lumber industry now wastes raw material which if utilized would yield daily 40,000 tons of paper, 3000 tons or rosin, 300,000 gal. of turpentine, 600,000 gal. of ethyl alcohol, besides fuel to meet all requirements of the industry. Dr. Little discussed the recovery of these products. This very able paper will be published in full in our next issue.

The next paper was read by Mr. W. S. Landis on the production of ammonia from cyanamid. This paper will be found published in full elsewhere in this issue (page 87).

The last paper was read by Mr. Maximilian Toch on the barium industry. Mr. Toch discussed the various barium salts and emphasized the necessity of a protective tariff.

A report of the other sessions and social functions of the convention, as well as publication in full of several of the other papers read at the meeting, must be reserved for our next issue.

The Rubber Industry—II

BY ANDREW H. KING

In my previous article I discussed some of the more important points in regard to the production of rubber, its properties, the nature of its molecule, proposed methods for its synthesis and also reviewed the various theories of vulcanization. In the following article I will outline factory practice in general.

Washing

After the arrival of crude rubber at the factory, the first operation which it undergoes is washing. While plantation rubbers are shipped washed and dried, many African, South American, and other varieties arrive at the factory in a dirty condition. African rubbers are particularly offensive. Besides certain putrefying plant juices which are usually present, sticks, stones, clay, etc., are often to be found.

The dirtier grades are best washed in a machine much resembling the beater of the paper mills. The better grades are washed directly on the rolls, with or without previous steeping in warm water. The rolls are corrugated, usually two in number, and a strong stream of water is thrown down between them during the operation. The rubber is passed through the rolls until clear and thin. Fig. 1 shows a modern three-roll washer. It differs from the usual two-roll type in the addition of an extra roll. This gives it an increased capacity which is said to be double that of the common type.

Drying

The wet sheets as they come from the wash room are dried either by vacuum dryers or by hanging in a warm room. Some companies do all their drying by vacuum, while others claim that the heat is injurious and use the older method. Sometimes both methods are used, it being the custom to hang everything strong enough to support its own weight, and vacuum dry the remainder. When hanging is resorted to, the sheets are hung in rows in a steam-heated, well ventilated room. This room must be darkened so as to retard oxidation. The temperature is ordinarily kept at 27 deg. C., but this is often found a little high for the cheaper grades of rubber. With good ventilation, drying is completed in three or four days, after which the rubber is milled, sheeted, and rolled up for compounding.

Compounding

As was stated previously, rubber has a reticular or network structure. It is this fact which makes com-

pounding possible. Each little loop of the net holds its quota of material. Obviously the larger the volume of compound added the farther apart the rubber nuclei are pushed, and the more strain is placed on the little connecting filaments. Therefore, the stiffer and less elastic becomes the product. Primarily compounding is based on volume percentage. Therefore, the more light pigment present the harder is the article. Hard valves almost always contain considerable quantities of such fillers as fossil flour, aluminium flake, etc. By analogous reasoning we see that heavy pigments which have a small relative volume give the opposite properties. Snappy elastic articles are produced by the aid of such fillers as litharge, barytes, zinc oxide, etc.

In compounding, as in the other branches of the industry, the price factor is paramount. It is the aim of the rubber chemist to always use material of just the necessary quality but no better. It is an economic sin to use Para rubber where shoddy will do just as well. The uninitiated must not get the idea that raw rubber properly vulcanized is the very best. The principal factor in determining a compound is its intended use. The degree of elasticity, toughness, strength, and resistance to abrasion must all be known before a satisfactory compound can be prepared. These properties all depend to a greater or smaller extent on the material used in compounding.

A constantly increasing variety of compounding materials finds application. There is little change, however, in the number of inorganic fillers. Very few materials are added just to fill up space. Most of them impart certain definite properties which may be used as a basis for classification, as follows:

Fillers Only.—This group embraces the various grades of rubber substitute, shoddy, ground rubber waste, and also certain inert mineral fillers such as whiting, barytes, and to a certain extent zinc oxide.

Rubber substitutes are the products derived from various oils such as rape, corn, linseed, etc., by one or the other of the following methods: First, sulphonation, the oil is boiled with sulphur; second, it is treated with sulphur chloride; or third, it is blown with air while at the boiling temperature or oxidation is effected by other means. Practically all white substitute is made by the use of sulphur chloride. Quite frequently sulphonated oils are blown. Substitute when properly prepared has a slight amount of "give," but almost no cohesiveness. It mixes easily in a compound and its purpose is simply that of a cheapener.

Shoddies will be discussed later.

Those Having a Hardening or Toughening Action.—Fossil flour, aluminium flake and other low-gravity materials act as tougheners, as explained in the foregoing. Zinc oxide, lithophone and calcined magnesias also have this property. Because of this function it is customary to find even 50 per cent or over of zinc oxide in the tread of an auto tire. Lime and litharge have a decided hardening action. It is not uncommon to find around 25 per cent litharge or 15 per cent lime in a hard valve.

Those Giving Dense, Non-Porous Mixtures.—Under this head come those materials which find application in articles which have to withstand water, steam, air, etc., under pressure. Mineral rubber, which belongs to the bitumen class, finds perhaps the greatest use in this respect. Tar and paraffine also are used.

Accelerators.—Those substances which hasten vulcanization are known as accelerators. It is quite obvious that the addition of a substance which cuts down the period of vulcanization increases a factory's output and also the profit. Their action is catalytic and they simply hasten the reaction between sulphur and rubber. Under this head come various oxides, the most important

FIG. 1—THREE-ROLL WASHER

being lime, magnesia, litharge and zinc oxide. Their relative accelerating power is shown by the order in which they are named. Lime finds considerable favor in this country, while the European preference is mostly for magnesia. Litharge is perhaps the most used of any. Lately organic accelerators have come into prominence. Dittmer claims that all organic bases having dissociation constants greater than 10^{-4} act as accelerators, regardless of constitution. To date the most important published ones are: Tetramethylenediamine, urea derivatives, carbon bisulphide addition products and piperidine.

Those Having a Softening Action.—Various oils, such as rosin and palm, are sometimes added in small quantities to soften a stiff stock for sheeting or for use on a tube machine. Heavy mineral oils, such as vaseline, are also used. It is the aim to keep away from saponifiable oils as much as possible.

Those Having a Sticky Tendency.—In building up articles such as tires, where many layers of thin sheets are used to make up a section, it is quite necessary for proper vulcanization that these layers stick tightly together. It is therefore often necessary to increase the stickiness of uncured stock by the addition of such substances as crude turpentine, tar, various pitches, etc. This factor becomes of more importance in the manufacture of frictions; i.e., fabric coated and impregnated with rubber compound.

Pigments.—The most important white pigments are lithophone and zinc oxide. In preparing a white stock it must be remembered that no lead compounds can be used since lead sulphide (black) is formed on vulcanization. The chief red pigments are: Crimson antimony sulphide, mercuric sulphide or vermilion, iron oxide and certain lakes. Antimony sulphide is much used in the production of non-blooming articles, such as auto-inner tubes of the best grade. By blooming we mean the tendency for the free sulphur to come to the surface and give a thin, dirty white scum of colloidal sulphur. Other pigments are prussian and ultramarine blue, chrome yellow, chrome green, etc.

As would be expected, compound receipts are quite valuable, and rubber companies go to considerable trouble to keep them secret. They are empirical and

FIG. 3—OPERATION OF MIXING ROLLS

have been worked out by experiment. However, it can be said that with certain few exceptions most articles can be analyzed and the compound deduced by an experienced rubber chemist.

The correct proportions of rubber, sulphur and fillers are weighed out in the compound room. The batches are customarily of 100 lb. each. They are made up in galvanized iron pans and sent to the mixing room. It is hardly necessary to state that all mineral fillers must be ground very fine.

Mixing

In general the construction of the mixing rolls is similar to those used in washing, except that the surfaces are not corrugated. Fig. 2 is a photograph of a small set of mixing rolls. The usual factory size is from 35 to 45 in. in length, and 12 to 16 in. in diameter. The gearing is differential, the front roll running at 18 to 20 r.p.m., and the back at 20 to 25. During the operation the front one is kept slightly hotter than the back. This in conjunction with the slower speed keeps the plastic mass on the front roll. Both rolls are fitted with means of steam heating and water cooling, which are used when necessary. Set screws which operate on the front roll are used to give the desired distance between the rolls.

The first operation in mixing is to properly "break down" the rubber. The rolls are heated to a moderate temperature and the rubber passed through a number of times, until it becomes smooth and plastic but not sticky. It then covers the forward roll as is shown by 1, Fig. 3. When this condition is reached, the rolls are brought closer together, thus forming what is called the "bank." This is designated by 3 in the above-men-

FIG. 2—SMALL-SIZE MIXING ROLLS

FIG. 4—24-IN. THREE-ROLL CALENDER

FIG. 5—OPERATION OF CALENDER

tioned diagram. Since the rubber heats up spontaneously on breaking down, it may be necessary to cool the rolls.

Shoddy is frequently broken down on separate rolls and added at this point, or the rubber and shoddy may be broken down together. Any oils or sticky material are usually added at this point. The attendant, aided by a short knife, cuts off pieces of the batch and throws these over and over on the rolls until a homogeneous mixture is effected. He then adds the powders as the mineral fillers are called. The bank acts like a third roll rotating in the opposite direction. It aids considerably in securing a good mixture.

The cutting and throwing process is repeated and finally the stock is removed, left to cool down slightly and passed through the mills, which have been opened a trifle so as to insure an even mixture. Following this the stock is sheeted for convenience.

The aim of the mixer is to have his batch well mixed before adding the mineral fillers, and to proceed as rapidly as possible from this point to avoid any overworking of the rubber lest it lose considerably in nerve.

Mixing machines are sometimes used. They consist essentially of inclosed rotating arms. The rubber is first broken down alone and the powders added. The operation is almost entirely automatic. Mixing machines find favor where considerable quantities of fine light material have to be handled. However, many old rubber men do not favor these machines, and claim that stock so mixed is apt to be deficient in nerve due to overworking or else poorly mixed.

Calendering

The object of the calender is to change the dough, or stock, as it is called, in the mixing room into sheets of even thickness, since it is from these sheets that most all rubber articles are made. Fig. 4 shows a "three-roll calender." The rolls are massive, correctly turned, and fitted with means for heating or cooling. Screws are provided for adjusting the distance between the rolls. Calenders are usually directly connected to a motor. Herringbone gears find the greatest favor, since they insure a more uniform speed. Altogether the calender is an expensive machine, and should be kept in use most of the time.

Fig. 5 illustrates the operation of the calender. The stock after being properly warmed up on a warming mill is fed in between rolls 3 and 4. By proper regulation of temperature it is caused to adhere to the middle roll, leaving the top and bottom ones clean. A strip of cloth called "liner" is taken from reel 2 and passes between the middle and lower rolls to reel 1. The sheeted rubber as it passes between these rolls is re-

ceived by the liner, which carries it to reel 1 where they are wrapped up together, the liner preventing the layers of rubber from adhering. By means of knives pressed against the middle roll, the sheet may be cut into strips of any desired width.

Frictioning

Frictioning, which consists of impregnating duck or other cloth with rubber compound, is also done on the calender. The only difference is that the rolls now travel at different speeds, the bottom one revolving at about two-thirds that of the middle roll, thus causing a wiping action. The duck is first well dried by passing it over steam-heated pipes in a duck drier. It passes through the calender from reel 2 to reel 1, as described under calendering sheets. The soft dough is forced into the pores of the duck first from one side, then from another. When it is desired to give a skim coat the rolls are opened a trifle and the friction passed through just the same as in sheeting. This places a thin layer of rubber on the friction on only one side.

Rubber Cement

The making of cement is rather an important branch of the rubber industry, as will later be appreciated.

Cements are made for all sorts of purposes. Those intended for cold vulcanization contain, of course, no sulphur. For patching a very good cold curing cement is made by swelling Para rubber in a suitable solvent. However, it is customary for cements to be made from compounded stocks, the purpose deciding the character of the compound. The chief solvents are benzole (90 per cent), gasoline (70-76 deg. B.) and carbon tetrachloride. The best results are given with benzole.

The stock or rubber from which the cement is to be made is first thoroughly milled. It is then sheeted and cut into fairly small pieces. These are placed in a churn with the required amount of solvent. After some time the rubber swells and forms a typical colloidal solution.

The grade of cement depends upon: First, the quality of rubber used. The addition of Pontinac or other highly resinous rubbers gives a thick, viscous cement of little holding power. Second, the kind and amount of solvent used. And third, upon the amount of mineral filler present in the stock.

Vulcanization

Vulcanization is effected by two principal methods. The first, hot process, is by heating rubber with sulphur. And the second, cold process, consists of treating it with a dilute solution of sulphur chloride.

Hot Process

This is effected in three principal ways. The first, heater cure, subjects the article to the action of live steam under pressure. The second, press cure, subjects

FIG. 6—DIRECT STEAM OR OPEN HEATER

it to hydraulic pressure and heats it indirectly by the steam-heated faces of the press. The third method, called the autoclave press, is a combination of the first two. The important factors in hot-process work are time and temperature. The latter is expressed in pounds per square inch steam pressure. Factory cures read so many minutes at so many pounds of steam, as 30 at 30 for example.

Live Steam Cure

Fig. 6 shows a direct steam or open heater. It consists of an autoclave equipped with a pressure gage, thermometer and self-regulating valve. An article to be cured by this method must first be wrapped tightly with a wet cloth. This is narrow and resembles both in appearance and application a bandage. Schidrowitz claims that where possible the live steam cure is best, since the steam seems to act as an accelerator. This method can not be applied to articles containing much oil substitute, owing to the saponifying action of steam at high temperature. Care must be taken not to release the pressure on the autoclave too rapidly lest the article become porous. The loss in time and heat occasioned by blowing off is quite considerable.

Press Curing

Fig. 7 shows a small multiple press. The heads A, B and C are heated by live steam under pressure. C is directly connected to the piston of the hydraulic press. In regard to this method, Schidrowitz makes the statement that in general, with given heat conditions, the better result is obtained by higher hydraulic pressure. The even distribution of pressure permits the production of relatively large articles where homogeneity is desired. Another advantage of the press is that the steam and hydraulic pressure can be regulated separately. Its great advantage is the difficulty in controlling the temperature of the heads due to condensation. If one face is hotter than the other the surfaces will not receive the same degree of vulcanization.

Autoclave Press

As stated previously, this method is a combination of the two above described. Articles to be cured are

FIG. 7—SMALL MULTIPLE PRESS

FIG. 8—SECTION OF AN AUTO TIRE

subjected to hydraulic pressure while contained in an autoclave. For example, auto tires which are cured in this manner, are built up on forms, clamped in molds and laid flat in the autoclave, the floor of which forms the head of the press. The molds are subjected to pressure between the top of the autoclave and this piston head. Steam is turned on just as in live-steam curing. For auto tires the hydraulic pressure amounts to around 1000 lb. per square inch.

Cold Vulcanization

In this process, rubber is vulcanized by the action of sulphur chloride, S_2Cl_2 . A 2 to 3 per cent solution in carbon bisulphide, CS_2 , or in carbon tetrachloride, CCl_4 , is used. Articles over 4 mm. thick cannot be cured in this manner since by the time the interior was vulcanized the surface would be over-cured and brittle.

The Manufacture of Tires

This subject is so broad that a complete discussion is entirely beyond this article. Ten years ago, when the tire industry began, they were made complete, that is, without a separate tube and casing as is the practice at present. This method was very expensive and tires were hard to make and hard to repair.

If the reader will refer to Fig. 8 we will take up the construction of an auto-tire casing, and consider the various parts and the necessary properties of each.

The principal parts are: Fabric, cushion gum, side strip, breaker strip, bead and tread.

Fabric.—Duck is fricated as previously described. It is commonly cut on the bias, and the tire roughed out on a form. This is made of heavy cast iron, since it is not removed until the tire is cured, and must therefore stand the high pressure of the press. Numbers 4

FIG. 9—SECTION OF TRUCK TIRE

and 5 show the layers of fabric. In good casings the fabric is made from long fibered or Sea Island cotton. The friction stock is very good, containing considerable rubber, no shoddy and as a rule no sticky materials. Much depends on the fabric, for it is the backbone of the tire.

Cushion Gum.—The gum cushion is indicated by 8. Its purpose is to add resiliency to the casing. It is a narrow strip of very good rubber, and as is shown, goes around directly beneath the point where the tread and the road surface make contact. It ordinarily contains around 80 per cent rubber.

Side Strip.—The side strip, 3 and 7, covers the sides and extends up under the tread to the gum cushion. It is not necessary to use such good material at this point. We usually find about 50 per cent rubber.

Breaker Strip.—This, 2, is a loosely woven piece of very strong cloth. It is placed over the gum cushion and covers the ends of the two pieces of side strip, thus tying them together. This is its purpose.

Bead.—The bead, 6, consists of a ring of hard rubber either with or without reinforcement by steel cable. Its shape depends on whether straight side or clincher rims are to be used. It is made up separately and applied between the layers of fabric.

Tread.—The tread, 1, is the most important part of the casing. It must be tough and hard but not brittle. Being in contact with the road surface, its wearing power decides the life of the tire. Because of the high degree of toughness necessary, one will usually find in it considerable quantities of zinc oxide. Ordinarily around 50 per cent is used to about 40 per cent rubber. The remainder is sulphur and miscellaneous filler.

The procedure of building up a tire casing is then as follows:

The operator begins with the fabric. The bead is placed in position between the layers. Next the gum cushion is applied. The side strips cover the sides and are bound together by the breaker strip. The tread goes on last. It must not be taken that any large sections are put on at once. Each separate part, except, of course, the breaker strip, is made up of a number of thin layers.

A tire casing so prepared is taken to the curing room, clamped in a mold and placed in an autoclave press for vulcanization. The period ranges from one to two hours at 45 to 55 lb. of steam. Where non-skid tires are being made the mold has depressions corresponding to the studs desired. The hydraulic pressure forces the tread into these, so that when the mold is removed the studs stand in relief. After trimming and wrapping the tire is ready for shipment.

Inner Tubes

A casing so prepared requires a strong elastic and air-tight inner tube. For this purpose a stock containing around 80 per cent rubber is used. The filler may be antimony golden sulphide, if non-blooming tubes are desired, or it may be simply zinc and iron oxides. Gray tubes have varying composition, depending on the maker's experience. The stock is sheeted very thin and the tube built up lengthwise on a mandrel by rolling. It is wrapped with cloth and cured in live steam. After splicing the valve is set in place and it is ready for use.

Solid Tires

Fig. 9 illustrates a section of a truck tire. These are usually built up on a ridged steel rim. D indicates the hard base, which is very nearly ebomite. Its purpose is to bind the tire to the rim. C is the elastic part and serves the same purpose as the air of a pneumatic tire. B is the next layer and is slightly tougher

than C. A is the tread and must be very strong and tough. It usually contains 40 to 50 per cent rubber, 2 to 4 per cent sulphur and the rest mineral filler.

Solid tires are also cured in an autoclave press.

Belting

Duck for belting is dried and frictioned as has been described. It is cut lengthwise into strips whose width depends, first on the size of the belt, and second upon the method of manufacture. One manner much used is to form the inner plies of strips having the same width as the belt. These are stacked and placed in the middle of a strip of double the width. They are next drawn through an opening having flared edges which fold the bottom strip over the top and form a butt joint. The belt is then passed between rolls which press the plies firmly together. At the same time the joint is covered by a narrow strip of rubber. While some of the most expensive belts are made without covers, it is usually the practice to have them. In fact, on some grades of conveyor belts even a gum filler is placed in the center of the belt. When the belt is to have a cover, this is commonly calendered on to the outside ply of duck before application to the belt.

Another method which is said to give a stronger belt is to cut each strip of duck twice as wide as the belt. The first strip is folded on itself, so as to form a butt joint. This strip is placed on the next with its joint down. The process is repeated until the belt has the desired thickness. The top joint is covered with a narrow strip of rubber or a cover placed on the belt.

The belt is cured in two steps. First it is tightly coiled and wrapped so that only the edges are exposed. It is then placed in a large heater where it is subjected to the action of live steam. When the edges are cured it is finally vulcanized in a long press. It is tightly stretched and cured in sections of from 10 to 30 ft. in length.

With conveyor belts the cover is always made of good material, but for transmission it is customary to use cheap covers and put the most expense into the friction, so that the plies of duck will be firmly held together.

Balata Belts

A discussion of rubber belting would not be complete without mention of balata. This substance, while having the same chemical formula ($C_{10}H_{12}$)_n as rubber, has almost no elasticity. Its behavior with heat is also quite different. At slightly over 70 deg. C. it softens, and by heating it a little higher duck may be impregnated with it. A balata belt is built up just as previously described under rubber belting, using, however, sheets of this treated duck. Successful operation depends considerably on keeping the balata at the proper temperature for working. When the desired thickness of belt is reached it is subjected to hydraulic pressure in a moderately heated press, thus forcing the balata substance well into the pores of the fabric. When it cools the balata sets and the plies are firmly bound together.

Balata belts are, as a rule, very good. The use for which they are best fitted is that of running under damp conditions.

Hose

This forms one of the most important branches of the rubber industry. Like the manufacture of tires, this subject is also so broad that we are unable to go deeply into it. The subject may be sub-divided as follows: Cotton jacketed, braided, and wrapped.

Cotton Jacketed.—This includes the various grades of fire hose, and is made up of a rubber tube with either a single or double cotton jacket. The tube is made from a calendered sheet, cut wide enough to give the proper

FIG. 10—52-FT. COMBINATION HOSE-MAKING AND WRAPPING MACHINE

circumference and a small lap. This lap is cemented and the tube given a semi-cure. This fixes the cement and also gives the tube enough strength for subsequent operations. The cover is woven separately. It is placed on a long table and a rod passed through it. This carries a cord, to which is attached the tube. The workman pulls the tube first through cement and then through the cover. The coat of cement is called the backing. Then he fills the hose with steam under pressure, which expands it, thus forcing the cement well into the cover and at the same time vulcanizing the rubber.

Braided Hose.—This variety is of practically recent introduction, but is growing in popularity and seems to be very good. Garden hose is one example of this class. The tube is run on a tube machine. For this purpose a soft stock is necessary. It is warmed to a sufficiently high temperature on the rolls to make it plastic, and in this condition it is forced through a die which may be adjusted to give any desired thickness of wall. A worm similar to that used on a sausage machine carries the stock forward and forces it through the die. In this manner hose of any length can be made. For this reason it is sometimes called continuous hose. Cheap gas tubing, and, in fact, most all small size single wall hose, is made in this manner.

Having formed the tube on the tube machine, it is then led through a braiding machine, where fabric is braided around it. The tube may or may not have been coated with cement, depending upon the kind of stock used and also on the purpose of the hose. The operation may be repeated as often as desired. When the required number of plies is produced the hose is sent through another tube machine, where the cover is placed on it in much the same manner as the tube was formed.

Vulcanization is effected in a press. During the operation air pressure is maintained inside the hose, which forces the rubber well into the meshes of the loosely woven braided fabric.

Wrapped Hose.—In this class I will include all those varieties of hose made up of a tube, cover, and friction. The friction is simply duck, coated as previously described under frictioning. Under this head come many varieties of hand-made, machine-made, and semi-machine-made hose.

All varieties are, however, built up on a mandrel. The tubes used may be made from sheets as described under cotton hose, or may be run on a tube machine. In this case they are placed on the mandrel by the aid of compressed air.

Short length varieties, such as air-brake and tank hose, are mostly machine made. This machine is not very complicated and consists principally of three rollers, two on the same plane and the other immediately above and half-way between the other two. The mandrel with the tube is placed on the rolls, the correctly cut strip of friction applied, the top roll let down and

the machine started. The tube is quickly wrapped. The cover is put on in the same manner. Armored hose is made by placing a spiral of wire between the plies as desired.

Long length hose is made in just the same way, except that here the machine is much longer. The length is usually 52 ft. and the hose is made in 50-ft. lengths. Fig. 10 is a photograph of such a machine. Hose made in this manner is wrapped with cloth and cured in live steam.

Molded Goods

This group includes valves, gaskets, and thousands of cheap articles. These are built up on a mold and cured in a press. Because of the low price at which they are sold, much attention is given to efficiency and speed of operation.

Dipped Goods

Under this head come rubber gloves, some surgical goods, and other thin rubber articles. They are built up on a form. A single carrier holds often as high as 100 of these. After dusting them with soapstone they are dipped in rubber cement. After drying the process is repeated until the desired thickness is produced.

Such articles are cured while on the forms by dipping in a solution of sulphur chloride; that is, by cold vulcanization. After curing, they are well washed, first with water, then with sodium carbonate solution, and finally with water. After drying they are peeled off the form, dusted with soapstone, and are then ready for shipment.

Spreading

Under this head comes the manufacture of proofed textiles. The process consists of spreading a very thin layer of rubber evenly over the fabric.

The spreading machine is a long, steam-heated iron table, provided with rollers at either end. The cloth as it is unwound from one roll passes under an iron "doctor," where it receives a certain quantity of cement. It then travels over the surface of the table, where the solvent is evaporated. The process is repeated until the desired thickness of coat is obtained.

Since considerable solvent is used in spreading, the tables are covered by hoods which lead to a refrigerating system, where most of it is recovered.

Such material is cold cured by passing it through sulphur chloride solution. The product is well washed and dried.

Shoddy

At various places in this article mention has been made of shoddy or reclaimed rubber. This branch of the industry is very large and the material finds application to a more or less extent in all branches of rubber practice except tire making. It has been said that two-thirds as much rubber scrap comes back to the factories as the crude rubber which they receive. How many times rubber is used over and over again is not known.

but it is undoubtedly a large number, and forms a good illustration of the reincarnation theory. However, as it is successively used it descends in the scale of value. Tire scrap furnishes the best grade, since it is made from the best of rubber and seldom contains any shoddy. This goes into other materials, such as steam hose, which in time wears out and comes back to be made into still a lower grade.

A true reclaiming process would give back the rubber in its original condition, minus the sulphur which was chemically added on during vulcanization. So far no such process has been brought forth. What is done is merely the freeing of the rubber from the fabric and depolymerizing it so that additional sulphur may be added and the material revulcanized. The alkali and acid processes are the most important.

Alkali Process.—The rubber scrap is finely ground between rapidly rotating knives. This material is placed in long cylindrical drums fitted with paddles. Here it is heated for around twelve hours with a 10 to 20 per cent solution of caustic soda. This treatment removes all saponifiable organic fillers, such as vegetable oils and substitute, and also the free sulphur. The fabric is destroyed and rendered soluble. The particles of rubber are secured by screening the tank liquor. They are well washed on a washing mill. After working a little they stick together and may be sheeted. The sheet is dried either by vacuum or by working on a hot mill. If the scrap used was rather low grade, it may be necessary to add tar, heavy oil, or other material to give it cohesiveness.

Acid Process.—This process is the same as the alkali, except that a dilute solution of sulphuric acid is employed instead of caustic soda. The product is not considered equal to that of the alkali process, and oil must be added to give it the desired degree of cohesiveness.

CONCLUSION

In this and the previous article I have endeavored to outline briefly the most salient points in respect to this industry. Rubber is a close competitor with steel in the number of things which may be made from it. It surpasses steel in the range of properties obtainable. The industry is of great importance, and the future will doubtless call upon it more and more.

The Mechanical Principles of the Blast Furnace—II

BY J. E. JOHNSON, JR.

The Support of the Charge Column

The support of the charge column is made up of at least four elements. First, the upward pressure of the gas. Second, the friction of the charge on the sides of the shaft. Third, the vertical upward thrust against the charge from the downwardly converging slope of the bosh walls. Fourth, flotation in the molten mass of iron and cinder in the hearth. To these we might almost add a fifth, the dragging of the pasty zone against the walls at the top of the bosh, but this may be counted as a part of the friction, especially as we have no means of measuring either.

The weight of the charge column is very generally over-estimated by those who have not made calculations upon it. It is ordinarily assumed that this weight is 50 or 100 lb. per square inch, but obviously this is not true. If we estimate that three-fifths of the charge by volume is coke with a specific gravity of 0.45, and two-fifths ore and stone with a specific gravity of 2.5, we shall have a column 1.18 times the specific gravity of water. Taking the height from the tuyeres to the

stock line of a modern furnace as 70 ft., the water pressure corresponding to this height is 30 lb., which would correspond to a weight of charge column of 35 lb., if the materials descended to the hearth in the condition in which they are charged. But as a matter of fact the ore loses about 25 per cent of its weight in the form of oxygen carried off by the ascending gases, while the limestone loses 40 to 45 per cent of its weight through decarbonization. Moreover, in many cases the bulk of the ore is vastly increased by the great volume of extremely light, flocculent carbon deposited upon it by the action of the gas. As a net result the weight of the charge column is greatly diminished, while considering only that part of it down to the base of the shaft, its diameter and area are greatly increased by the outward batter of the furnace still further reducing its weight per square inch.

In my paper "Notes on the Physical Action of the Blast Furnace" before referred to in this serial, I have embodied some calculations on this subject which are probably just as applicable to present conditions as they were to the conditions on which they are based, and are therefore quoted.

In order to have a concrete example on which to base calculations, let us take, as representative of present conditions, the Isabella furnace, of which the more important data are given in Mr. Gayley's paper on the dry blast. The lines of this furnace are shown in that paper.

Let us assume, for an average of summer and winter conditions, that the output is 400 tons per day and the burden per 10,000 lb. of coke is 22,000 lb. of ore and 5500 lb. of limestone; the coke per ton of iron is 1900 lb. and the ore per cent through the furnace, to agree with the above assumption, 53.6 per cent.

The total content of 18,090 cu. ft. are divided as follows: 1193 cu. ft. in the hearth, 3087 in the bosh, and 13,810 in the shaft above the bosh.

Assume that coke weighs 28 lb., ore 135 lb., and limestone 90 lb. per cubic foot—figures sufficiently exact for our purpose, then the volume of a charge will be 357 cu. ft. of coke, 163 of ore, and 61 of stone, or 581 cu. ft. in all. Each charge weighs (as charged) 37,500 lb.; hence the initial average weight per cubic foot is 64.5 lb.

The weight of stock in the shaft of the furnace can easily be calculated from the weight and volume of the charge given above, but the result so obtained is entirely too high for several reasons. In the first place, the ore swells enormously in volume under the action of the gas and the deposition of carbon. Secondly, the oxygen of the ore is nearly all removed, lightening it about 30 per cent. Thirdly, all the CO₂ of the limestone is driven off, lightening it 44 per cent.

It is impossible to express the sum of all these effects with quantitative accuracy, but if we assume that the ore doubles in volume, and that the limestone decreases 44 per cent in weight by the time the charge has reached the top of the bosh, and neglect all the other conditions, we shall certainly be on the safe side in estimating the total lightening effect.

This gives a final reduced weight of 47.2 lb. per cubic foot, and if we assume the change to have occurred uniformly as the charge descended, we can calculate the weight of stock in the shaft, which will be, on this basis, 755,000 lb.

The difference of pressure between the tuyere-zone and the stock-line is 14 lb., and this is evidently all used up in forcing the gas formed at the tuyeres through the column of stock.

In the absence of knowledge as to the rate at which the pressure falls, we may reasonably assume that it is proportional to the distance traversed. This gives a

loss of 2.6 lb. to the top of the bosh, leaving a pressure at that level of 11.4 lb. more than at the stock-line. Leaving out of account what goes on below that level, it may be observed that, since the stock exerts a resistance of this amount to the passage of the gas, the gas must also exert a resistance of an equal amount to the passage (descent) of the stock, since action and reaction are always equal and in opposite directions. In this resistance to the descent of the stock will be found the cause of slips.

The pressure of 11.4 lb. on an area of 21 ft. diameter gives a total pressure of 568,000 lb.; but the difference of pressure is all that counts, and each zone is a little larger than the one above, so that the whole difference of pressure only acts on a central area equal to that of the stock-line. A deduction of 184,000 lb. must therefore be made from this 568,000 lb., and the net resistance offered to the descent of the stock by the blast is thus 384,000 lb., which is more than half of the entire weight of the column of stock. From the unbalanced remainder must be deducted the weight necessary to overcome the friction of the stock on the walls, which it is not practicable to estimate in figures. Probably it is not less than from 10 to 20 per cent of the weight of the column, and may easily be more. Assuming it to be 15 per cent, it amounts to 113,000 lb., which added to 384,000 gives 497,000, or about two-thirds of the total weight of the stock-column.

Under normal circumstances the remaining third of that weight is enough to bring the column of stock down; but if any local derangement takes place, and the pressure ceases to fall at a regular rate, we have a condition the trouble-producing power of which is cumulative, for owing to the increased resistance, the flow past the obstructed point is reduced, and with it the friction and counter-pressure below, while owing to the damming action of the obstruction, as the engine continues to blow the same quantity of blast, the pressure soon runs up, and as the velocity is reduced the high pressure that normally exists only in the lower part of the furnace extends up under the obstruction. This compresses the obstruction more, and forces it more tightly against the furnace walls, while at the same time, by reason of the greater pressure, it becomes denser, and offers still greater resistance to the passage of the gas, which in turn augments all the other effects, until the furnace is "stuck" tight. The "plug" is in a conical passage and cannot yield backwards, and things remain in this condition while the stock below continues to settle until a cavity is formed underneath the "plug." Finally, through some accidental weakness in the obstruction, or through the slacking of the blast and reduction of the pressure under it, which allows the plug to come loose, the condition is broken, and the suspended mass falls.

As to the cause of the violent ejections of stock, some of which take the bell along, there has been much speculation, and various explanations have been made, none of which have seemed adequate. The true explanation seems to be that the whole furnace below the plug is a reservoir of compressed gas (this being especially true of the cavity formed under the obstruction), and when this latter gives way it is like knocking out the keystone of an inverted arch under pressure—the instant the arch is broken the compressed gas has ample energy to carry away, in its sudden escape, part of the overlying stock.

The greater the cavity the longer the "blow"; while the further down in the furnace the obstruction lies the higher the pressure under it is likely to be, and the greater is likely to be the mass of material above it through which the gas must make its exit and portions of which it will carry along.

To the initial increase in resistance to the passage

of the gas several causes may contribute; but, if the furnace is not scaffolded, the most important one is the deposition of carbon-dust through the splitting up of the CO into CO₂ and C. Both the extent of this action and the time of its beginning vary greatly with the character of the ore through which the gas passes, as has been shown in various papers read before the Institute and elsewhere. It has also been shown that the action proceeds with great rapidity when it has once begun, thus localizing it in some cases to a certain restricted zone in the furnace, both below and above which the charge is more open—below, by reason of its downward movement and the increased shaft-diameter reached thereby; above, because no carbon has yet been deposited in it. The slips thus tend to be localized in this zone; and hence most of the slips from a given furnace, which slips habitually, would have about the same degree of violence. Practice shows this to be the case.

The resistance of the gas column to the descent of the charge has been treated above as if it existed only above the top of the bosh, though as a matter of fact it exists all the way down to the tuyeres, but has not as great an effect in the bosh as it has above that region for the reason that in the latter region the area on which the smaller blast pressure acts is greater than that on which the larger pressure acts, that is to say, the pressure at the top of the bosh is smaller but the area of this zone is larger, while the hearth pressure is larger but its area is smaller. Therefore the difference in the products of these two is much less important than it is in the case of the bosh zone and the stock line where the greater pressure exists over the greater area and the smaller over the less.

In further explanation of the lifting action of the gas current on the charge column it may be remembered that one of the approved methods of lifting grain consists in delivering it into a vertical pipe up which a current of air is traveling at a high velocity. This is not in any way connected with lifting water by suction, through the removal of air, which is limited to 34 ft., but may be carried on practically without reference to the height. But when we find even approximately what the actual velocity of the gas current is, we realize that the present action is not altogether similar to this.

We have already seen that the velocity through the shaft is approximately constant so we can determine it roughly by reference to the hearth conditions only.

Assume a furnace of ordinary dimensions with a 16-ft. hearth blown with 45,000 cu. ft. of blast as measured by piston displacement or, say, 40,000 cu. ft. actual at atmospheric temperature and pressure compressed to 15 lb. pressure, and heated to 1200 deg. The absolute

volume becomes $40,000 \times \frac{1660}{530} \times \frac{15}{30} = 62,600$ cu. ft.

The area of the hearth empty is 200 sq. ft. but this is filled with coke, through whose voids only, the blast must pass. Assuming these conservatively as one-fourth of the total (see below) we have a net area certainly not to exceed 50 ft., through which all the blast must pass. This would give a velocity of $\frac{62,600}{50} = 1250$ ft.

per minute, but it must be remembered that this refers to the voids in the coke by itself and takes no account of their obstruction by molten iron and slag which as we shall later see is very great. If we assume that they amount to 50 per cent of the original area we shall probably be safe and this would double the velocity, making it 2500 ft. per minute or approximately 30 miles per hour and it may well be that this figure is too low rather than too high.

This velocity alone, however, is not sufficient to ac-

count for the drop in pressure in so short a distance but there is another factor of great importance; the roughness of the passage through which the gas column must pass, the "wetted surface" of the conduit (the stock column) is almost infinite and when we remember the vast effect of a slight increase in the roughness of any conduit on the friction of the fluid passing through it we have no difficulty in understanding the pressure drop even though the velocity be no more than 30 miles per hour, and, of course, the pressure drop is the direct measure of the lifting power of the charge rather than the velocity. In other words the action in this case is rather that of a leaky piston than the transportation of loose material by a rapid air current.

The Friction on the Walls

The effect of the friction on the walls is very great and must not be ignored though we have no means of estimating it accurately. It has been found in cylindrical grain bins that something like two-thirds of all the weight of the grain is taken on the side walls, but we cannot expect so large a percentage to be carried this way in the case of the blast furnace because the stock is kept in a more or less violent state of agitation by the current of gas rising through it. A strong upward current of gas produces a tremendous effect in the internal friction of a loose mass of solid matter particularly one containing much fine material, the agitation of the smaller particles makes them act almost like a liquid and exercise a corresponding influence on the larger particles. A mass of dry sand which might stand at a slope of 20 deg. when quiescent would not stand on one of 5 deg. if agitated by a current of air from below. On the other hand, the pressure of the charge column against the sides may be very much greater than what we should expect from its weight alone, that is to say, the pressure which the walls would receive if considered as a vertical retaining wall for an embankment. This is because of the tremendous swelling which frequently takes place in the ore due to carbon deposition.

These conditions make it exceedingly difficult to apply even our slight knowledge of the internal friction of such materials as compose the furnace charge to determining the effect of wall friction quantitatively, but we do know that the charge sometimes hangs in the furnace at a height far above the beginning of the pasty zone and sometimes remains hanging even when the blast is taken entirely off. This can only be due to wall friction and indicates that this may sometimes exceed 100 per cent though undoubtedly its normal amount is very much smaller.

THE SUPPORT DUE TO THE UPWARD COMPONENT OF THE REACTION OF THE BOSH WALLS

Obviously if the bosh walls were continued down until they met in a point the inverted cone so formed would support the stock column completely, and the portion of this cone which actually exists furnishes its portion of support, this, of course, ignores all questions of flotation from the liquid in the hearth which we may exclude for the present. Thinking only of the steep slope of the bosh and of what a small frustum of a complete cone it is, we might be inclined to dismiss as insignificant the amount of this support especially in view of the modern tendency to build furnaces with large hearths and extremely steep, short, bosh slopes. But even in the most extreme of these furnaces this would not be correct, for the amount of this support is obviously proportional, other things being equal, to the difference in the area of the zones projected into a horizontal plane. Even with a 22-ft. bosh and 17-ft. hearth this difference is 40 per cent of the bosh area and it

seems reasonable to assume that 40 per cent of whatever unbalanced pressure may exist down to the tuyere zone is taken by the bosh slope even in this case. Incidentally this indicates that a change in hearth diameter of 1 or 2 ft. may have a considerably greater effect in the mechanical operation of the furnace than we might at first glance suspect. That this is true we have an abundance of experimental evidence.

In considering the shape of the furnace we shall presently note that as blast pressures have risen supplying more support for the charge column, hearth diameters have increased leaving the bosh area smaller and so supplying less support. This at least suggests that the proper descent of the charge column only takes place when the sum of the resistances thereto does not exceed a certain total.

The Flotation of the Charge Column in the Liquid

This is an exceedingly complicated question. It is rather illuminating to consider the volume of molten material in the hearth at its maximum. Let us assume that a 500-ton furnace casts four times per day and that one-fourth of the total cinder, or 300 lb. per ton, is in the furnace before cast, and that the hearth is 16 ft. in diameter which gives an area of 200 sq. ft., all about in accordance with modern practice.

We may assume that the volume of iron at the high temperature at which it exists in the furnace is 5 cu. ft. to the gross ton, and that molten slag weighs 150 lb. to the cubic foot, so that 300 lb. of slag have a volume of 2 cu. ft., which added to the 5 cu. ft. of molten iron makes a volume of 7 cu. ft. per ton. One hundred and twenty-five tons of iron would therefore correspond to a volume of liquid of 875 cu. ft., or sufficient to fill the hearth to the depth of a little less than 4½ ft., in other words not very much over half way up to the tuyeres.

On this basis we could dismiss the idea of flotation altogether if we considered the charge column to end at the tuyeres, but as a matter of fact we know that it does nothing of the kind, and that it must settle until it rests upon the hearth bottom, or until it is floated by the liquid in the hearth. Of course, if the stock column were only 8 or 10 ft. high it would readily be floated by the liquid, but when we consider the great height of superincumbent stock resting upon it, and forcing it down, we realize that it may be forced to the bottom of the bath at least in furnaces with a small blast pressure and shallow bath.

The result of forcing the stock column down into the bath is to raise the level of the liquid very greatly since the latter can occupy only the interstices in the coke. We do not know what these amount to exactly, but some careful experiments I made several years ago showed that the voids in thoroughly mixed crushed ore were about 33 per cent, while the percentage of voids existing between spheres closely packed is about 35 per cent of the volume of the spheres or about one-quarter of the volume of the space occupied. We may therefore assume without chance of great error that the percentage of voids in the coke as it exists in the hearth and bosh do not exceed 33 per cent of its net volume, or one-quarter of the total, which means that the height of the liquid must be four times as great as that estimated above or nearly 18 ft., which would bring the liquid well above the tuyeres if the coke column extended down to the bottom of the hearth. This is at least partly in accordance with the facts, since, of course, we know that the cinder will flow back into the tuyeres and rise in the penstocks to a considerable height if the blast be taken off before first "flushing" the cinder out of the furnace.

It is instructive to make an estimate of the floating

effect of the liquid bath even though we must use approximate figures.

Assume coke to weigh 28 lb. per cubic foot loose and to contain 25 per cent of voids, then its weight "solid" is 37 lb. per cubic foot. The weight of slag per cubic foot is as above given about 150 lb. and of iron 450 lb.; on the basis of the weights of these in the hearth and their combined depth of $17\frac{1}{2}$ ft. in the interstices of the coke, the depth of slag alone would be 5 ft. and that of the iron $12\frac{1}{2}$ ft. The buoyancy of the coke in slag per cubic foot of space is three-quarters of $(150 - 37)$ or about 85 lb. and for the whole depth of the slag it is 425 lb. per square foot upward thrust, for the iron it is three-quarters of $(450 - 40)$ or about 300 lb. per cubic foot and would be twelve and one-half times as much if the coke were submerged in the iron to the bottom of the hearth or 3750 lb. per square foot, this added to the 425 lb. per square foot due the submersion in the slag makes 4175 lb. per square foot or 29 lb. per square inch, which added to the 12 lb. due the blast pressure above the top of the bosh would make 41 lb. per square inch of total upward pressure on the base of the stock column or *considerably more than its total weight* without any allowance whatever for friction on the walls or support on the slope of the bosh. It is perfectly clear therefore that the weight of the stock column is not sufficient to force it to the bottom of the hearth when the latter contains much molten material but that it is submerged only to such a depth as supplies the upthrust not furnished by the other three forces. That the buoyancy of the base of the charge in the liquid in the hearth is a decided factor is proved by the fact that furnaces always settle very much more, immediately after cast than they do at any other time. Very frequently a furnace will settle perceptibly even as a result of flushing, and there is no reason to doubt that this is due to the removal of a portion of the buoying action of the liquid.

That the charge column does not rest on the bottom at least before cast time a very interesting proof has recently been given by Mr. F. L. Grammar.* If gaging prove that a furnace is settling regularly at the rate of 30 in. per half hour previous to cast and if during the half hour occupied by cast it settles 60 in., then obviously it could not have been resting on the bottom at the beginning of cast.

There is much reason to believe that the liquid slag not only stands in the furnace above the level of the tuyeres but that it is blown up through the interstices in the coke to a level many feet higher. The viscosity of the slag is considerable, and the blast has difficulty in making its way through it, as anyone will realize who has seen or even heard the slapping and blubbery which accompanies this action when it takes place under abnormal conditions when the slag is standing at a high level in the bosh and only a little blast passing through it (conditions which only exist with a badly deranged furnace) and we know that if the blast be taken off the furnace too quickly, even though the slag be below the level of the cinder notch when it comes to rest, we are more than likely to have the cinder come back in the tuyeres, which, of course, can only happen if at least a part of the slag has been well above their level.

In order to form a picture in more easily comprehensible terms I have sometimes thought that we might take a glass tube some 2 in. in diameter, and insert into it, 1 in. from the bottom, some $\frac{1}{4}$ -in. nozzles piped to a supply of air under slight pressure, fill the tube with water to a level half way up to the air nozzles, pour in sufficient granulated cork or other light substance to fill the tube for a height of 10 or 12 in., and then blow

air through the air nozzles in sufficient quantity to keep the water which is raised up around them by the descent of the cork, in a lively state of agitation. It is obvious that the cork would be supported partly by this flotation in the mass of bubbles into which the water would be converted, and partly by the ascent of the air through its interstices, and perhaps some of its weight would rest on the bottom of the tube.

Such a mental picture shows us how impossible it is to estimate exactly the value of each component in supporting the column of cork.

Limitations to the Size of the Furnace

The use of the formula for blast pressure as a tool of investigation enables us to discover the reason for certain facts of practice not otherwise easily understood. If furnaces be built larger they must obviously be blown with a proportionately increased quantity of wind if they are to yield results commensurate with their size, and in fact this is always expected of them. There are a few furnacemen who have built furnaces much larger than is customary for the tonnage which they desired to produce, but this practice is very rare though extremely sensible and advantageous. Generally considerations of corporation policy force the manager to produce an amount of iron approximately proportional to the volumetric contents of his furnace. Proceeding on the assumption that this condition must be met, we obtain the following results: W , the quantity of blast per minute, to be proportional to the capacity of the furnace, must vary as D^3H with the 22-ft. x 90-ft. furnace and 45,000 cu. ft. of wind $\frac{W}{D^3H} = 1.03$, and any other furnace with dimensions D_1 and H_1 must be blown with $1.03 D_1^3 H_1$ cu. ft. of wind to maintain this proportion. Then from the general formula we have

$$P_1^3 - P_2^3 = 0.0080 \frac{(1.03)^2 (D^3 H)^2 H}{D^3} = 0.00085 H^3.$$

For the 22-ft. x 90-ft. furnace the pressure figures out as follows:

$$P_1^3 = 216 + 0.0008 \times \frac{(45,000)^2 \times 90}{22^3} = 216 + 0.0008 \times \frac{2,025,000,000 \times 90}{234,000} = \frac{80 \times 202.5}{26} + 216 = 624 + 216 = 840 \therefore P_1 = 29 \text{ abs.} - 14.7 = 14.3 \text{ lb., which is just about the actual pressure for these conditions.}$$

For a furnace one-half larger and blown with proportionately more wind we should have then $P_1^3 = 216 + 624 \times (1.5)^3 = 216 + 2100 = 2316$ or $P_1 \text{ abs.} = 48.1$ or a gage pressure of 33.4 lb. That is to say, if the shape and relative dimensions remain the same, the difference of the squares of the absolute top and bottom pressures increases as the cube of the height. Therefore, if we build a furnace 50 per cent larger in all its dimensions than the present 90-ft. x 22-ft. furnace, and blow it with a proportionately increased volume of wind, we shall have a blast pressure of 33.4 lb. as against the normal pressure of the present size furnace of 14.3 lb., or nearly two and one-half times as much for an increase of 50 per cent in height.

The result of this is two-fold. First, we receive no return whatever for the power expended in compressing the blast. It is a necessary evil and nothing else. Therefore the power expended for this purpose is wasted from more useful purposes. Moreover the investment required to blow higher pressures increases all along the line, not quite in the same proportion, but still at a very rapid rate, and the interest and depreciation on this surplus investment is therefore an absolute loss. Second, the regular descent of the stock is made increasingly difficult and a point would soon be reached where it would become impossible.

*Private communication.

Referring to the detailed calculation of the Isabella furnace given above it will be seen that the pressure per square inch of the stock column, referred to the area of the top of the bosh, figures out to about 15 lb., or to put it a little more accurately that the blast pressure in this case is just about half of the total stock column pressure without undue allowance for expansion of the ore. A greater height from the top of the bosh to the stock line may reasonably be assumed to yield a proportionately increased pressure of the charge column. This in our assumed furnace 50 per cent larger in all dimensions than the modern 90-ft. x 22-ft. furnace would give a stock column pressure at the top of the bosh of about 22.5 lb., while the blast pressure at that point, on the basis of a uniform drop in pressure from top to bottom, would be one-fifth less than the tuyere pressure of 33.4 lb. or about 27 lb. In other words the gas pressure alone at this point would be materially more than the weight of the charge column, and the latter would therefore be unable by any possibility to descend regularly, since we have seen that there are three other important factors resisting it.

It is easy to see then that there are natural laws which prevent building furnaces of more than a certain height and corresponding diameter, and it is a matter of record that furnaces over 100 ft. high have been less successful than furnaces of about 90 ft. high, so that in one case furnaces 106 ft. high were cut down to 90 ft., and at another plant which started with furnaces 100 ft. high, the next ones, built after several years' experience were made 90 ft.

These facts taken in conjunction with the blast pressure and stock column figures given indicate that 90 ft. is about the limit of the size of furnaces which may be blown to full capacity. If larger furnaces were built it would be necessary to blow them with less than the proportionate amount of wind. This would probably be a wise move within moderate limits since the larger furnace blown with the same quantity of wind, of course, requires a smaller pressure and allows a longer time in preparation for the stock, while the initial cost is nothing like proportional to the increase in capacity, and the smaller pressure required means a smaller investment in power plant.

Against this on the other hand is the fact that the radiation from a given furnace is practically constant, and therefore the faster the furnace is driven the less the radiation loss per pound of iron. From the data given in the article on thermal principles we know that the radiation and cooling water losses are 10 or 12 per cent. This means that if we made only half as much iron in the same size furnace these losses would run up to about 20 or 25 per cent.

Looking again at the other side we have reason to believe that in present practice furnaces are often probably blown a little harder than the rate at which the coke consumption is a minimum. A little fuel is sacrificed for the sake of increasing the output since this keeps down capital and labor costs to some extent.

The Shape of the Furnace

This is a subject which should properly be treated under operation, but the considerations we have discussed may be expected to exert certain influences upon the shape of the furnace, and some of these we may now consider.

We may well ask ourselves why has the furnace the shape which a slow and painful evolution has given it in all parts of the world: a cylinder at the top and bottom, the latter surmounted by an inverted cone of quite rapid outward batter, and this in turn by a frustum of an upright cone of a much slower inward or convergent batter?

We have already seen that the shape of the furnace is approximately that which gives a uniform velocity of ascent to the gas column, its shape has been worked out upon purely empirical grounds, so that while this condition may be due to a coincidence it is more probably due to a relation of cause and effect entirely unknown during the development. There are certain other considerations of great importance and while we cannot attach quantitative values to them, and do not know all of their effects, we can point out some of their influences at least in a qualitative way.

The common base of the two conical portions of the furnace or the base of the short cylinder which connects them is universally known as the top of the bosh. What is this point?

It is in my judgment the zone in which the combustion of the oxygen of the blast to CO is complete, or viewing it from the opposite direction, it is the point at which the coke in its descent begins to be burnt by the blast. I have already discussed to some extent the fact that the lower part of this region is hotter than the upper, which at first sight it should not be if the combustion of the carbon to CO were going on uniformly throughout the zone, and I have given Professor Howe's explanation to me of this fact, that in the lower part of this region the coke was burned in the local and temporary excess of air partly to CO₂ with resulting high temperature, but that as this CO₂ rose through the excess of fuel in the bosh it was deprived of one atom of its oxygen by another atom of carbon, the whole forming CO instead of CO₂, and this reduction of CO₂ to CO is a distinctly cooling reaction. It is, therefore, to be expected that the upper portion of the bosh should be cooler than the lower portion, and this idea is not only not in conflict with, but is a confirmation of the conception that combustion of coke to CO is going on throughout the bosh, that being in fact the region of the furnace devoted to that purpose, in other words the combustion chamber. [Since the above was written I have been informed by John N. Reese of Youngstown of the results of some extensive investigations carried on by him, in which analyses of gas taken from the bosh at increasing heights showed contents of oxygen gradually diminishing and finally disappearing just about the top of the bosh. This is an independent experimental confirmation of the view here given far stronger than I had dared to hope for, and in my judgment forms convincing proof of its correctness.]

Above the top of the bosh we may assume that the material is in a "dry" condition. That is to say, neither the slag-forming materials nor the iron have begun to soften and become sticky. They then pass through a zone in which the sticky condition prevails, and finally as they become hotter and as the different slag-forming materials become more intimately mixed and therefore more fusible, both they and the iron pass out of the sticky condition into that of complete fusion with consequent liquidity and freedom of movement. It is obvious on a little consideration that this sticky zone is likely to obstruct both the passage of the gas upward and that of the stock downward, and in order that these shall not be prevented from moving in their appropriate directions it is obviously desirable that more room and slower velocity of travel should be provided at this point than at any other. This then should be the top of the bosh.

Granting that the top of the bosh is the point where the combustion of the blast to CO is complete and is also the point at which the solid materials enter the pasty state, this is obviously also the point where the gas generated in the hearth ceases to expand by combustion and drops below the critical temperature [since that is

by definition the free-running temperature of the slag]. From this zone upward it must contract by cooling through contact with the stock, and while, of course, it receives some increase in volume from the CO_2 of the limestone, this is much less than the contraction due to cooling.

From the top of the bosh downward the considerations which effect the shape are the decrease in the volume of the gas current as we approach the tuyeres (that is to say, its increase in volume as it rises from them), and the shrinkage, and eventual disappearance, of the coke.

We have then at the top of the bosh conditions which reverse within a short distance, first we have an increase in diameter necessitated both by the volume of the gas and the conditions of the stock column and then a decrease in diameter necessitated by opposite conditions, but it is evident that this reversal can not occur instantly and that instead of the two cones meeting at a fairly sharp angle, as it was once customary to have them do, there should be a transition zone either barrel-shaped as was once the custom, or a cylindrical section as is now the general practice.

Mr. Reese has recently pointed out to me that there is another reason for a cylindrical zone in this region which is that on some irons and some ores the furnace works on a very much more refractory slag than on others, and in consequence the pasty zone will be reached at a much higher level in one case than in the other and the maximum diameter at both heights can only be obtained by a cylindrical section.

To this Mr. Reese adds the valuable general law that the more infusible the slag the lower the bosh must be, which is borne out in a very broad way by all practice, both coke and charcoal.

Charcoal furnaces are ordinarily run with a very acid and fusible slag as compared with normal coke furnaces. Owing to its fusibility this slag melts at a higher relative elevation in the furnace than do ordinary coke slags. For this reason the top of the bosh of these furnaces should be higher relative to their height than that of coke furnaces. It has been found by experience that the height of the bosh of a charcoal furnace above the hearth level should probably never be less than 25 per cent of its total height and may be 28 or 30 per cent, whereas that of modern coke furnaces is considerably less than 25 per cent.

It is probable also that the cylindrical section in the pasty region has an advantage for another reason. The pasty zone must be penetrated by the charge column from above and by the gas from below, as long as this zone remains flat and horizontal, these actions can go forward without difficulty, but if the zone becomes arched either upward or downward due to greater or less activity in the center than at the side as is easily possible, then we have a condition of danger. For if the edges of the zone abut against a conical surface converging on the concave side of the curved pasty zone we shall have an arch formed which will tend to close up under the action of either the gas current or the stock column and obstruct the action of the furnace, perhaps even scaffolding it. But if the edges of the curved pasty zone abut against a cylindrical surface there is no "skewback" or support for such an arch and its chances of doing harm are much reduced.

CONDITIONS AFFECTING THE SIZE OF THE HEARTH

We can most conveniently consider the development of the size of the hearth from the chronological point of view.

In cold-blast charcoal furnaces, the earliest type developed, the hearths are extremely small, being only

2 ft. to 3 ft. in diameter for a corresponding bosh diameter of 8 ft. or 9 ft. In these furnaces the pressure of the blast is nearly always low so the shape of the gas column as affecting its resistance to the descent of the charge is less important than in furnaces with higher pressures. I am led to believe that this small hearth is necessary to obtain a sufficient concentration of heat to melt the iron and slag, for as shown by Fig. 1 on page 789 Vol. XIII (Nov. 1, 1915) these furnaces produce a very small amount of hearth heat per pound of fuel with their low critical temperature. Even with very high fuel consumption they are barely able to avoid freezing up, in other words their theoretical combustion temperature is but little above the free-running temperature of the iron and cinder.

In warm and hot-blast charcoal furnaces the theoretical combustion temperature is brought well above the melting temperature of the iron and slag, and the furnaces, therefore, are not forced to concentrate their heat in a very small space as is the cold-blast furnace. On the other hand, larger outputs are demanded of them, and this means a larger hearth in which to burn the fuel; it also means a greatly reduced upward batter of the bosh, and a much closer approximation of the hearth and bosh diameters to that required by a constant gas velocity.

In coke furnaces we go a step further in the same direction, hotter blast is used and more heat developed per pound of fuel. Therefore, we have a higher theoretical combustion temperature and less need for concentrating heat in the hearth, much larger outputs are demanded and consequently a larger hearth is necessary to burn the fuel, while, owing to the higher temperature of the blast entering the hearth, the ratio of increase in volume at the top of the bosh is smaller and the hearth can therefore be relatively larger. This is the general line along which furnace development has actually taken place.

The concentration of heat in the hearth is a factor often ignored in modern practice although so vital to success in the cold-blast charcoal furnace, but in spite of this neglect it is a factor which must receive consideration when foundry and high silicon irons are to be made. We desire a high temperature of the iron so that it may take up a high percentage of silicon, and we are not at liberty to obtain this high temperature by making a limey, and therefore relatively infusible slag, because the lime would resist the entrance of the silicon into the iron. Some other way must therefore be found of securing a concentration of heat in making such irons, and this is done by making the hearth of relatively small diameter which gives a corresponding concentration of heat in that region with a comparatively small and therefore hot and active column of gas rising from it, down through which the iron must pass and be correspondingly heated on its path into the hearth.

CONSIDERATIONS AFFECTING THE DIAMETER OF THE STOCK LINE

The considerations affecting the diameter of the stock line are first, the relative volume of the gas there as compared to that at the top of the bosh, on the constant velocity theory; second, the swelling of the charge due to chemical action as it descends; third, the necessity of providing sufficient disengaging surface for the gas so that its velocity may be kept down and the carrying over of an excessive amount of the fine portion of the charge prevented.

The small gas volume of cold-blast furnaces causes little or no trouble by carrying over fine ore and fuel from the top of the furnace, and therefore the latter can have a relatively small area and the shaft of the

furnace can be given a rather sharp outwardly descending batter, $1\frac{1}{2}$ in. to the foot, or even more.

The top diameter of warm and hot-blast charcoal furnaces is not increased as much proportionately as might be thought, for the smaller quantity of fuel used produces a proportionately smaller quantity of gas as compared with the total charge which it is required to heat up, the consequence is that most of the sensible heat is taken from the gas so that it is discharged from these furnaces quite cold, relatively speaking. I have seen top temperatures on a hot-blast charcoal furnace run for weeks below 212 deg. Fahr. The contraction of the gas due to this cooling offsets to a considerable extent the increased rate of blowing of such furnaces, and makes a relatively small stock line sufficient in this case also.

In coke furnaces using Mesaba ore the controlling factor in stock-line diameter is the velocity of the gas issuing from the surface of the charge. If this exceeds a certain rate fine particles of ore and other materials are picked up bodily and carried over with the gas current causing very serious inconvenience and loss in utilizing the gas and a loss of ore which is normally important and may easily become excessive.

If the output be great the gas volume must clearly be so likewise within narrow limits and the only way to reduce its velocity is to increase the area of the throat.

A. N. Diehl has stated that the surface of the charge in ordinary practice using a large percentage of Mesaba ore is constantly in agitation with particles rising and falling all over the surface and this is obviously the limit of gas velocity permissible.

The condition is precisely similar to that in a steam boiler where it has been found absolutely necessary to provide a given amount of disengaging surface for each cubic foot of steam produced under penalty of having the steam pick up and carry over such quantities of water as to make the operation of the boiler dangerous if not impossible.

This necessity of keeping within a certain limiting top velocity has exercised a potent influence on furnace lines, for the top diameter irrespective of all other conditions must be large enough to keep the issuing velocity below the danger line. I am inclined to believe that this consideration has forced the use of larger stock lines on hard-driven furnaces than other considerations demanded and that if we were satisfied to blow a little slower on a given furnace we could probably contract its stock line to the benefit of the operation as a whole.

In some ores the swelling action is slight and in others very great. In the experiments of O. O. Landig (*Trans. A. I. M. E.*, Vol. XXVI) some ores caused a deposition of carbon from CO five or six times the original volume of the ore, this being sort of a catalytic effect. The effect of such an increase in the volume of the ore tends to swell the whole charge and as it cannot secure more room above or below it must have room to expand laterally if it is not to become jammed in the furnace by this action. The furnace should therefore expand downward at quite a rapid rate to prevent the possibility of such jamming.

The diameter of the bosh being controlled by hearth and bosh conditions we are not at liberty to secure expansions by enlarging that and in consequence we have only one method of increasing this batter which is by carrying the stock line diameter of the furnace down as close as we dare to the point where the swelling of the charge begins or roughly to the bottom of the warming and drying zone, so concentrating the outward batter into a shorter zone and making it more rapid. This is the line along which the modern development of furnace lines has taken place. At the same time I have never

felt perfectly sure that it would not be safe to increase the bosh diameter and so secure greater batter. It is worth noting also that too large a stock line defeats its own end, as far as keeping down flue dust is concerned, for nothing makes so much flue dust as irregular descent of the charge, "slipping," and if the furnace works "tight" in the zone of carbon deposition this will result in top slips and the production of much flue dust, while if the stock line be somewhat reduced the resulting increase in outward batter supplies more room for expansion and relieves the "tight" zone, so tending to reduce slipping.

CONSIDERATIONS AFFECTING THE BOSH DIAMETER

We have already seen that the diameter of the gas column at the top of the bosh for constant velocity is larger than the actual bosh diameters in common use and have indicated certain conditions affecting this, but the conditions are too many and too complicated and we do not know positively enough about them to permit drawing very definite conclusions. We do know that in earlier days boshes were very much larger, particularly in relation to hearth diameter, than they are now (see Fig. 7 and following) and the rapid batter of the shaft and flat bosh slope which resulted being continued until they intersected, with no intervening cylindrical section made rather a sharp internal angle where they met and it seems to be abundantly established by the experience of the furnacemen of that day that this was a very inactive region. Its area was so great that the gas velocity through it was very low; accordingly it was a fruitful zone for the establishment of scaffolds which might content themselves with filling up the useless space, but once formed, were likely to grow too large and were certain to be irregular so that their influence on the work of the furnace was generally, though not invariably, bad. In my own experience I have seen a furnace whose bosh was too large for the work it was doing and whose work was less satisfactory than smaller furnaces had been.

On the other hand, many furnaces were built about thirty years ago with extremely small boshes, only one-fifth or less the height of the furnace in diameter, and some of these have been built in recent years, but except on very hard and irreducible ores which swell very little during reduction, they work with high pressure and consequent hanging and irregularity, therefore with high coke consumption, and in general very unsatisfactorily.

It would seem, therefore, that while the diameter for constant gas volume may not be and probably is not the correct diameter for the bosh, it is not very far from it and is certainly closer to it than some actual bosh diameters which have been used, both larger and smaller. It is evident from the discussion of hearth and stock line diameters above that both of these must exert an influence upon the bosh diameter in the directions and for the reasons pointed out. It seems certain, therefore, that the bosh diameter must be a compromise resulting from these considerations and many others, notable among these being the height and angle of the bosh; for given these and the diameter of the hearth the diameter of the bosh obviously becomes absolutely determined, as a consequence we cannot change one of these three alone but must change at least two and this fact greatly increases the difficulty of determining the controlling conditions.

In a general way the necessity of more room for expansion for the charge in its descent and for the gas volume in its ascent through the bosh would seem to indicate a somewhat larger bosh diameter than is now customary, as none of the influences mentioned indicate

FIG. 20—FURNACE NO. 1

any danger from a moderate step in this direction, especially with the increasing hearth diameters now being used.

Of course, in so abstruse and difficult a matter the test of time and experience is the only safe guide.

The evolution of practice from the early days of the anthracite iron industry to its decline about thirty years ago is well shown by Figs. 7 to 22 from Mr. F. Firmstone's paper.

About a generation ago many furnaces were built with a small hearth, a high and very steep bosh, and a top much larger than the hearth. The evolution of standard practice at the two largest furnace plants in the country using Lake ores is well shown by Figs. 23 to 36, reproduced from H. A. Brassert's paper "Modern American Blast Furnace Practice" before the American Iron and Steel Institute in 1914.

The boshes have been lowered virtually 50 per cent, the hearth has been increased about 50 per cent, and the angle of the bosh has gone through a cycle swinging from 79 deg. down to 72½ deg. and now back again to 80 deg. The top diameters have been changed but little, as have the heights, practically all the later ones being 90 ft. These changes have taken place with an increasing rate of production, the net result of which has been to make an increased tonnage per furnace of three to one over the practice of a generation ago.

With this increased output has gone necessarily an increased volume of wind. The resulting increase in pressure has increased the rapidity of combustion and reduced

the amount of space necessary for that operation, so that the zone of fusion and the top of the bosh have steadily fallen. To a certain extent it is proper to say that the blast heats available have increased and that therefore there is less relative increase in volume of the gas column at the top of the bosh as compared with that at the tuyere plane and this has coincided with the increase in the hearth diameter, as it should on the theory of constant gas velocity; at the same time it must be recognized that the desire to produce a greater tonnage per furnace with the consequent necessity of burning more coke, and affording more room for this, has been the chief cause for the latter change.

As to the considerations which effect the slope of the bosh, we know but little. At the beginning of the period covered by the set of profiles reproduced from Mr. Brassert's paper it was quite customary to use very small hearths and steep bosh angles in furnaces much smaller in maximum diameter in the bosh and also at the top than number 1 of this series. For a period of years and within limits it may be correctly said that a proportional increase of both hearth and bosh diameters took place, as it properly should on the theory of constant gas velocity, and this, combined with the lowering of the bosh, had the effect of greatly reducing the bosh angle. That this effect was highly beneficial in some cases, I have seen demonstrated so unmistakably as to leave no room for doubt, but now, as above noted, the tendency is to return to bosh angles of between 77 deg. and 80 deg., and with these angles it is possible to use high blast temperatures with large percentages of Mesaba ore, something it was considered impossible to do for many years, for a reason of which many furnacemen convinced themselves by trial, that furnaces using large percentages of these ores would "stick" if given more than a very moderate amount of blast heat.

The reason for this action is not definitely understood as far as known to me. Presumably it results from the fine subdivision of the ore which, when in a partly reduced condition, enables it to form a plastic mass too early in its descent, if the furnace becomes too hot, and is analogous to the tendency of all furnaces irrespective of the ore they use to stick if they become excessively hot in the hearth.

Whatever may be the cause of this tendency it is now demonstrated that it may be overcome by steepening the angle and reducing the height of the bosh, presumably so as to furnish smaller resistance to the descent of the charge column and thereby counteract the tendency of the charge to hang from being sticky.

With the change in practice worked out at the South Chicago Works of the Illinois Steel Company, described in the papers of Messrs. Brassert and Mathesius, has gone an increase in the pressure-drop for penetration as mentioned earlier in this article. The increase is more than proportional to the hearth diameter through which it must act while the tuyeres used are very long, and it is probable that the resulting acute jetting action virtually builds up the inside of the hearth and on the lower portion of the bosh, owing to the effects described under the head of penetration.

Considering these two circumstances together it may be that the high penetration produces "phantom" bosh and hearth lines on which the furnace really works in operation, the bosh flatter, and the hearth diameter smaller than those provided in the construction and yet short and steep enough to prevent too great support of the stock by the bosh walls in the (upper) pasty zone, thus giving a certain amount of latitude in the working lines of the furnace, within which it may find those best suited to the conditions.

These views in regard to the South Chicago practice are intended merely to be suggestive, they must not

FIG. 21—FURNACE NO. 1,
REBUILT 1875-77

FIGS. 23 TO 36—SHOWING THE DEVELOPMENT OF BLAST FURNACE LINES FROM 1882 TO THE PRESENT TIME, AS ILLUSTRATED BY THE FURNACES BUILT AT THE
EDGAR THOMSON WORKS, CARNEGIE STEEL COMPANY AND THE SOUTH WORKS, ILLINOIS STEEL COMPANY

be considered as established. It must be noted also that this change has been accompanied with an improvement in the quality of fuel used which has enabled practice to be followed which would not have been so successful with an inferior fuel. The concentration of heat with a poorer fuel is not sufficiently great in so large a hearth and a tendency would arise that might be very troublesome for the hearth to build up in the bottom. Even now it remains to be demonstrated that a sufficient concentration of heat in the hearth can be made with these furnace lines to produce foundry and other high-silicon irons, furnaces of this type having made their records on steel-making irons low in silicon, and having definitely failed to produce foundry iron satisfactorily in some cases.

Reviewing all these complex considerations many of them obscure and difficult to understand and all almost virtually impossible to measure, it becomes evident that the mechanical principles of the blast furnace are not second in practical importance to the chemical and thermal principles and that if furnaces are to yield a satisfactory commercial result we must consider with the utmost care not alone chemical equations and heat balances which often largely take care of themselves any way, but questions of regular and uninterrupted descent of the charge column, leading to low fuel consumption, low flue-dust loss and regular product, of low and uniform blast pressure permitting the use of small and inexpensive power plants and small consumption of furnace gas, and other purely mechanical questions.

It is a safe statement that if one-half the scientific research had been expended on these practical mechanical questions that has been spent on chemical equilibria and lopsided heat balances the science and art of furnace operation would be far ahead of where they are to-day.

The Production of Ammonia from Cyanamid

A paper read at the Baltimore meeting of the American Institute of Chemical Engineers on January 12, 1916.

BY W. S. LANDIS

After working for many years on the problem of the fixation of atmospheric nitrogen in the form of cyanides and cyanamids, Professors Frank and Caro of Berlin were forced by the outbreak of the Boer war to turn their attention to the utilization of their products otherwise than in the field of precious metal extraction. A consequence of the then existing economic situation was the discovery of the process of transforming the cyanamid compounds into ammonia. United States Patent No. 776,314, granted Nov. 29, 1904, most probably represents the first American publication on this subject.

According to the specifications of this patent various cyanamid compounds and derivatives, including the crude form of the calcium salt sold under the name of lime nitrogen, when treated with steam or water in the proportion of three molecules of water to two atoms of the nitrogen in the cyanamid salt, will yield ammonia. It is recommended in the specifications that the reaction be carried out at temperatures from 160 deg. to 180 deg. C. in a closed vessel, though the claims of this patent cover temperatures above 100 deg. C.

There has grown around this process and its later refinements in the last fifteen years an extremely important ammonia industry. Naturally the greatest development has been in Europe, its home, and it is only within the past year that a plant comprising full-size apparatus has been in operation in the United States. In attempting to catalog the various plants throughout the world which have been converting cyanamid into ammonia in large-scale operations, I find that avail-

able information, particularly since the outbreak of the European war, is so incomplete that the listing in consequence was very inaccurate. It is certain, however, that the transformation of cyanamid into ammonia is successfully carried out in Norway, Germany, France, Switzerland, Italy and Japan, and prior to the war in Belgium, the bulk of the product going into ammonium sulphate for the chemical and fertilizer trade. Norway is producing large quantities of ammonia used in the Birkeland-Eyde plants for the production of ammonium nitrate; France has produced considerable quantities of anhydrous ammonia by this process; at the present time Germany is producing enormous quantities of nitric acid from this cyanamid-ammonia by a newly developed oxidation process, and is erecting cyanamid plants equipped with ammonia apparatus at various places.

The fixation of atmospheric nitrogen, chiefly due to our Government's policy in respect to water power development, has not been practised in the United States. During the year 1914 contracts were let in Germany by the American Cyanamid Company for the equipment of the largest single ammonia plant then projected or operating in the cyanamid industry, but the outbreak of the European war interfered with the shipment of this apparatus, nearly all of which was seized by the German Government for the purpose of providing for its own explosive requirements. It was possible to bring only a small portion of this equipment over to the States, where it was set up and put into operation, and is now producing several tons of pure ammonia gas per day. This plant has been in continuous operation here for six months without any signs of trouble whatever, and is considered to be most successful and satisfactory in every way.

RAW MATERIALS

The crude cyanamid or lime-nitrogen is now a well-known commercial product. The Canadian factory supplying the United States and its insular possessions with this product has a capacity of fixing nitrogen equivalent to 90,000 lb. of ammonia per day, and with the completion of certain additions now being made will be capable of supplying some 110,000 lb. of ammonia each 24 hr. The demands for this product, most of which goes into the fertilizer industry, are so great that the plant is now operating at its full rated capacity. It is therefore evident that the supply of raw material for an ammonia industry is in no sense limited.

Crude cyanamid, or lime nitrogen, the reagent used for the production of ammonia, is an electric furnace product, whose production has been described elsewhere* by the writer. This material as turned out of the furnace, contains nearly 25 per cent nitrogen in the form of CaCN_2 , 12 per cent CaO and 12 per cent carbon, with miscellaneous impurities derived from the various raw materials entering into its manufacture.

The other raw materials entering into the ammonia process are soda ash and hydrated lime. The quantities used are small, being approximately, $3\frac{1}{2}$ per cent and 2 per cent respectively of the weight of lime nitrogen used. Steam and power requirements which vary with the size of the plant are discussed later.

CHEMISTRY

On treating lime nitrogen with steam, ammonia is produced from the calcium cyanamid according to the following reaction:

The reaction is almost quantitative when carried out

**Metallurgical and Chemical Engineering*, vol. XIII, p. 213. (April, 1915)

on a large scale according to the process to be described later in detail. This reaction is exothermic in character, and while the exact heat of formation of calcium cyanamid has never been determined accurately, it is believed that the heat evolution from the decomposition of the cyanamid alone amounts to between 200 and 300 lb. calcs. per pound of ammonia evolved. This plays an important part in the present method of carrying out the process, inasmuch as after once starting the reaction under proper conditions it will proceed of itself, and, in fact, with such great velocity that only complicated and highly developed apparatus can take care of the gaseous products.

The process as carried out in the plant operating in the United States is essentially that described in the specifications of United States Patent 1,149,633, dated Aug. 10, 1915, "Process of Making Ammonia from Calcium Cyanamid."

In order to take advantage of the exothermic character of the reaction, as above stated, the process is made to take place in an autoclave partly under high pressure. This apparatus consists of a steel tank approximately 6 ft. in diameter, 21 ft. high and capable of operating under a working pressure of 300 lb. per square inch. It is provided with a powerful stirring apparatus. Into this autoclave is charged about 12,000 lb. of mother liquor derived from a previous operation (fresh water to start), and lime nitrogen is slowly fed into this liquor under continuous agitation. As the lime nitrogen contains always a fraction of a per cent of undecomposed carbid, acetylene is evolved during this dissolving of the lime nitrogen. A proper ventilating system is provided to remove this acetylene at such dilutions as will be non-explosive even if subjected to a source of ignition. The charging is usually carried on over a period of an hour so as to insure a thorough incorporation of the lime nitrogen with the solution and the breaking up of all lumps in the slurry.

When the lime nitrogen has all been added to the autoclave the reagents—soda and lime—are added for the purpose of increasing the efficiency of ammonia evolution, principally through prevention of the formation of polymeric forms of cyanamid compounds which are difficult of transformation into ammonia. The autoclave is then closed up, and steam is admitted for approximately 15 min., or until the pressure gage on the autoclave indicates three or four atmospheres, which shows that the temperature in the autoclave has been raised sufficiently to start the reaction at a fair rate of speed. The reaction then proceeds of itself, generating ammonia and steam in the autoclave, and it is necessary to relieve this gas accumulation by means of

FIG. 1—VARIATION OF COMPOSITION OF AMMONIA-STEAM MIXTURE DISCHARGE

FIG. 2—VARIATION OF RATE OF DISCHARGE

suitable valves to avoid excessive pressures in the apparatus. The rate of reaction becomes cumulative as the temperature rises, and this relief of ammonia and steam must be permitted. Under normal working conditions the pressure in the autoclave will rise to about twelve or fifteen atmospheres in the course of about 20 min. with the relief valve open. The pressure then drops off slowly, as the gas is discharged, the rate of discharge being usually regulated by the attendant at the valve so as to maintain a constant pressure in the ammonia line, and at the end of about one and a half hours from the start of the operation the evolution has usually stopped.

Nearly all of the cyanamid in the charge has been decomposed during this first period of the operation, but the solution is still highly charged with ammonia, which it is necessary to expel. A very small amount of undecomposed lime nitrogen may be left, particularly of polymerized forms, which yield up ammonia only slowly. The steaming operation is then repeated, this time introducing steam until the pressure of the autoclave goes up to six to eight atmospheres. The ammonia discharge valves are again opened until the autoclave is discharged, requiring a period averaging approximately one-half hour for this second discharge.

In order to insure practically complete evolution of all the ammonia in the autoclave it is advisable to again repeat the steaming to six to eight atmospheres for a third period, discharging as before. During this last period of steaming and discharge rarely over 2 per cent of the total ammonia as charged is evolved, and it can, therefore, be omitted if extraordinary demands on the capacity of the apparatus are made.

Extended studies of the course of this decomposi-

FIG. 3—VARIATION OF PRESSURE IN AUTOCLAVE

tion of lime nitrogen in the autoclave have been made both abroad and in this country, and are here reproduced in the form of charts. The discharge from the autoclave consists of a mixture of steam and ammonia, the composition progressively changing during the cycle. This variation in composition is shown for an actual operation carried out in this country in Fig. 1, in which the ordinates represent the percentage of NH_3 by weight in the ammonia-steam mixture discharged from the autoclaves, and the abscissa the time after start of the operation, analyses of discharge being made at approximately 3-min. intervals.

The rate at which ammonia is discharged from the autoclaves under operating conditions varies with the imposed condition. It has been found that most requirements are met by discharging at such rate as to maintain a constant pressure of steam and ammonia in the main leading from the autoclaves. Under such conditions the rates of discharge during a given operating cycle are represented by the curve in Fig. 2, in which the ordinates are the pounds of ammonia discharged per hour, and the abscissa again the various elapsed times from the start. In this case the charge in the autoclave was 7000 lb. of lime nitrogen analysing about 26 per cent equivalent NH_3 .

Where a uniform supply of ammonia is required it can be obtained by the insertion of a special type of gasometer in the system. Also suitable grouping of a number of autoclaves and cyclical operation of the same will assist greatly in obtaining a uniform rate of production without the use of such gasometer.

In Fig. 3 is shown a curve of the pressures existing in a European autoclave, slightly smaller than the one described above, and operating on a charge of 8000 lb. of lime nitrogen. The dotted lines represent the admission of steam, and the full lines the pressures as shown on the gage on the autoclave. The ammonia discharge valves of the autoclaves are opened where the lines are indicated double.

At the close of the operation the bottom discharge valve is opened and the mud contained therein runs by gravity into large suction filters of the well-known "Nutsche" type. Here the liquor is sucked off from the solid constituents, a thorough wash with water is given and the sludge removed to the dump. Under normal operating conditions this sludge when dried contains less than 0.2 per cent of equivalent ammonia, and about 65 per cent of CaO in the forms of carbonate and hydrate. It is dark gray or black in color, due to the carbon present, and finds application as an agricultural lime. The liquor removed from the filter is used in dissolving the next batch.

HANDLING THE GAS

In the manufacture of ammonium sulphate, as carried out extensively abroad, the mixture of steam and ammonia coming from the autoclave is led directly into an absorber and produces a high-grade white sulphate. This production of sulphate is much simpler than from ammonia liquor. Where the introduction of the accompanying steam is not permissible, as in the production of certain ammonia salts which cannot be subjected to high temperatures, or where the process involves subsequent evaporation and crystallization, the ammonia-steam mixture coming from the autoclave is passed through a simple rectifying column provided with dephlegmator and condenser, and there is obtained therefrom a practically chemically pure ammonia gas, saturated with moisture at the temperature of the condensing water. This rectifying column is self-acting because of the large quantity of steam admitted with the ammonia-steam mixture, and requires no attention whatever in its operation other than to shut off the cooling water to the condenser when not in use.

The ammonia derived from the column, as before mentioned, is practically chemically pure, and is used directly in a large number of chemical industries. The Birkeland-Eyde engineers absorb this ammonia gas in distilled water, forming a dilute aqua ammonia, which they add directly to their dilute nitric acid for the manufacture of ammonium nitrate, the product being of extraordinary quality. On the other hand, ammonium nitrate of equal grade may be produced directly from the ammonia gases dehydrated in the column without the water absorption step.

One of the large autoclave plants in France has been manufacturing anhydrous ammonia for years, and in addition to the above purification system they have installed an oil washer, charcoal filter and lime-drying boxes before liquefaction. The oil washer, the writer was informed, was installed to remove some very minute traces of an unknown organic compound, but he has inferred that the character and quantity of this impurity, from the manipulation of this apparatus, is largely mythical.

For the production of nitric acid from ammonia, the product as taken from the condensers attached to the ammonia column is so pure that no trouble is occasioned by the poisoning of the catalyzers used in its subsequent oxidation.

COMPLETE PLANT

An autoclave plant* of 15 autoclaves, such as supplied the Birkeland-Eyde Co., which is similar to those intended for this country, has a rated capacity of 75,000 lb. of ammonia gas per day. The general arrangement of the apparatus, piping, etc., is clearly shown here by the use of colored inks, and I am sorry that photographic reproduction does not bring out the details of these drawings so that they can be shown in a more convenient form. Owing to the present inability to obtain this apparatus from Germany, where it has been manufactured on an extensive scale, the American Cyanamid Company has redesigned the whole equipment, adapting it to American standards and manufacturing conditions, and is now building this equipment in the United States.

EFFICIENCY OF DECOMPOSITION

An extended study made by the writer a year ago of one of the European plants which had been in operation for a long time, showed that the transformation efficiency of the nitrogen in the lime nitrogen into ammonia was over 99 per cent. Our American plant is showing operating efficiencies covering a period of several months substantially equal to the above.

AUTOCLOVE PLANT

An economical autoclave unit is one of eight working shells. As the operating load factor on these autoclaves is very close to 100 per cent it is not necessary to supply more than one spare shell to this eight autoclave equipment to insure a full 100 per cent load factor. Such a plant of eight autoclaves would require a 300-hp. boiler. It was the old practice abroad to set the safety valve on the autoclave shells at 20 atmospheres and operate the boiler at this same pressure. In our own designs here in the States we have successfully operated at 125 pounds steam pressure without trouble and can take steam from a common plant main. Superheated steam is preferable for the purpose, but not absolutely necessary. There is in addition required for operating the lime nitrogen feeding device, the stirrers in the autoclaves, the vacuum pump and the air compressor, and miscellaneous sludge disposal equipment a continuous motor load of approximately 100 hp. (the connected

*Drawings of this plant were exhibited by the author at the meeting.

motor load would probably average about 200 hp., depending upon local conditions).

OPERATING COSTS

In the compilation of a cost sheet for the production of ammonia from lime nitrogen there is such great latitude in unit costs concerned that the writer is presenting rather full quantitative data, to which he is appending assumed unit costs. In most cases the assumed unit costs are averages existing before the outbreak of the European war, and to which an approximate return may be expected after its close. In any case they may be readily corrected to meet local conditions.

Lime nitrogen: 26 per cent ammonia. It is unquestionably the cheapest source of nitrogen (ammonia) in this country. The sales prices are dependent to an extent upon the quantities and deliveries contracted for. The freight is allowed at \$3.00 per ton of lime nitrogen shipped in special containers, which should cover the greater portion of territory in the United States lying within a 500-mile haulage radius of Niagara.

Caustic lime is to be air slacked on spot, 2 per cent weight lime nitrogen used assumed at \$6.00 per ton delivered.

Soda ash 3½ per cent of weight of lime nitrogen at \$16.00 per ton delivered.

Power, 100 hp. continuous at 1c. per hp. hour.

Steam at 30c. per 1000 lb., 60 per cent weight lime nitrogen.

Water, 2 U. S. gal. per lb. ammonia. As the larger part of this is used in condensers and coolers the greater proportion may be salt water. Assumed at 2c. per 1000 gal.

Labor and superintendence: Assumed at 300 men hours per day at 30c. per man hour.

Repairs and renewals: \$1.50 per ton ammonia, a record of long-time operations.

Interest: Assumed at 6 per cent on plant cost of \$120,000.

Depreciation: On plant cost of \$120,000 depreciated in ten years, say, 8 per cent.

OPERATING COST OF AMMONIA PLANT

Capacity 30,000 lb. ammonia per day, gas saturated with water at cooling water temperatures.

Item	Quantity	Rate	Per Day	Per Pound Ammonia
Freight		\$3.00	\$150.00	\$0.00600

COST OF PLANT

On account of the varied building conditions existing throughout the country it is almost impossible to give a detailed estimate of the cost of plant. A recent projection of such costs made by this company for a plant of this size, from which I have deducted the cost of land, foundations and sludge disposal, shows that an ammonia plant of the size herein described could be erected for about \$120,000. This plant is designed to produce an ammonia gas as its final product cooled to the temperature of the available water of the condensers, and, therefore, not strictly anhydrous. This figure further assumes that water and power are furnished the plant, and no provision is made for power or pumping plants.

Steel buildings with corrugated iron sides and roof, and of a type which have demonstrated themselves as fairly satisfactory for this service are included. The

limitations imposed by building laws and choice of architecture may force one to materially modify this estimate, as cheaper forms of construction may be used. On the other hand, many may prefer a more elaborate type of building than provided in the above estimate, which would materially raise this figure.

SUMMARY

The large number of installations operating with perfect success in various parts of the world for a number of years have demonstrated the commercial possibility of making ammonia from lime nitrogen. The plant in its present highly developed state is extremely certain in its action and simple to operate. The efficiency obtained in the transformation of the nitrogen in lime nitrogen into ammonia gas is upward of 98 per cent, or almost quantitative. The consumption of reagents is remarkably small, and they are cheap and easy to obtain in almost all parts of the world.

The quality of the ammonia produced by this process is not surpassed by any in the United States. It is chemically pure as produced and requires no further costly and tedious purification to render it available for the highest grade chemical products, or for the production of liquefied anhydrous. The actual cost of production of this high grade pure ammonia on a considerable scale, which enables one to take advantage of the lower prices at which lime nitrogen is offered, brings high grade cyanamid-ammonia into the market almost as cheaply as the more impure forms already found there, and very much cheaper than it is possible to obtain an equal quality of ammonia from gas-house liquor, the coke ovens, etc.

American Cyanamid Co.,
Niagara Falls, N. Y.

Non-Ferrous Metal Market

Copper—According to the Geological Survey the copper production for 1915 was the greatest on record. The smelter production is estimated at close to 1,400,000,000 lb. The average price for the year was about 17.3 cents as compared with 13.3 cents for 1914. At the present time no one but the producers knows how scarce the metal really is. Since our last report the price has risen from 21.75 to 24 cents although no enormous amount of buying has been recorded. The last quotation was 24 cents on Jan. 12.

Tin—Imports for the year 1915 from all sources according to the New York Metal Exchange were 47,835 long tons as compared with 40,887 long tons in 1914. The average price for the year was 38.66. During the last two weeks the market has been excited and spot tin and early deliveries have been difficult to buy. The price advanced from 39.12½ on Dec. 28 to 44.75 on Jan. 5 since when it has reacted to 41.25 to 41.50.

Lead—The production of refined lead in 1915 according to the Geological Survey estimate was 565,000 tons as compared with 542,122 tons in 1914. The maximum price was 7.56 cents on June 14, the average for the year being 4.7 cents as compared with 3.9 cents in 1914. During the last two weeks three advances have been made by the Trust. On Dec. 31 the price was advanced to 5.50 on Jan. 4 to 5.75 and on Jan. 7 to 5.90.

Spelter—The estimated spelter production for 1915 was 492,495 short tons as compared with 362,361 short tons in 1914. The market during the last two weeks has been quiet but firm, with prices practically unchanged at 17.42½ to 17.67½.

Other Metals—Aluminium is quoted at 54 to 56 unchanged. Antimony is scarce and is quoted at 42.50. Silver is quoted at 56½. Quicksilver has risen to \$175 per flask.

The Grading Industries

BY EDWARD S. WIARD

I have given the above title to certain industries, not because grading is the essential operation in them, being in most cases but an auxiliary one, but rather to discuss under this convenient title some mechanical problems which arise in industries in which grading is one of the necessary steps. Before the completion of the articles it will be seen how great is the scope of the "grading industries" and how much of interest there is in their history, statistics, technology and trade. The plan of the articles will be to describe first the "tools" used in grading. Following this portion of the articles, which will take up the theory of the action of grading devices and practical considerations governing their design and the kind of material for which they are especially suited, the grading industries will be taken up in alphabetical order.

The word "grading" is used in these articles in the sense of preparing material according to size or sizes, and in the majority of the grading industries the sizing is the finishing operation, following which products are ready for the market. In many cases they are ready for the consumer and in the rest they are ready for the initial operations of other industries. The majority of the grading industries have to do with the preparation of raw material which reaches the consumer indirectly through its use in other arts and manufactured products. Sulphur used in many arts and talc employed as a filler for wallpapers, for talcum powder, etc., are examples of graded products which reach the consumer indirectly. As examples of graded products which directly reach the consumer may be mentioned black gunpowder, flour and food products of many kinds, such as rice, peas, beans, coffee, etc. In the case of food products grading is done primarily to please the eye and to a minor degree for sanitary reasons. Crushed seed and fruit would invite decay. In the case of peas and beans uniformity of size also makes for uniformity of cooking.

Distinctions in Grading

In the subject of grading, distinction must be made between the breaking up of a granular or fragmental mass or masses of objects of the same or nearly the same general shape into a number of sizes, and the mere splitting of such masses into two, one fine and the other coarse, one or both being saleable but usually only the finer one. Where the fine material is the merchantable product the coarser part is either allowed to go to waste or, as is most commonly the procedure, it is subjected to comminution to obtain a complete yield as a fine product. This is usually done continuously; that is, the comminution means are closely connected with the separation means, the reject of coarse material from the latter flowing directly back to the comminuting devices. This mode of operating produces what is known as a "closed circuit," and what this means and its effect on the rate of feeding of the comminuting device is described in the reference below.¹

Examples of splitting grading can be found in the preparation of talc for paper filling and talcum powders, flour, artificial and amorphous graphite for pencil making and high-grade lubricants, pumice for scouring-soap powders, infusorial earth for incorporation with high explosives, separation of sand and slime in the cyanide process for gold extraction, preparation of pigments, etc. Some of the modes of effecting the splitting are by dry screening—flour, pumice and sulphur being examples of this mode of separation; by air separation—natural amorphous graphite and pigments

being examples of this mode of splitting. In both of these cases separation and comminution go on continuously, the end result being to reduce all the material treated to a finely divided saleable product.

In some industries the employment of a splitting grading or separation would yield a superior product, but the expense attending the use of separating means would be out of proportion to the value of the better product obtained. Again the possible means which could be employed would not be efficient, or the most effective process which could be employed would spoil the product made. In preparing feldspar for pottery purposes or abrasive soaps the finishing grinding is done in a tube mill. For the first purpose the spar is ground from four to six hours, when over 96 per cent will pass a screen with 200 openings to the linear inch. For soap purposes the spar may be ground for as long a period as ten hours. In these cases it must be evident that while a very finely divided product is desired there must be a large proportion of the spar which is ground unnecessarily fine in order to be sure that no grit remains in the finished material. If the spar were submitted to a water separation the fine material would have to be dried and it would be spoiled by caking. Efficient dry separation processes would not be applicable because of their expense and limited capacity. The best ground feldspar is worth about ten dollars per ton.

In the manufacture of Portland cement the use of a wet separation method would, of course, be out of the question, and dry separation by air would not be applicable for the reason stated above. As in the case of feldspar much material must be ground unnecessarily fine to be sure that all the product will be reduced to the proper limiting size which, in the case of cement, means that 75 per cent or over must pass a 200 mesh sieve. Portland cement has sold as low as \$0.65 per barrel weighing about 380 lb. How fine a cement particle must be ground has not been definitely fixed by experimentation but there is no doubt that there must be a certain sized particle below which in point of size all the particles are cementing material and above which they are not.²

An unusual separation occurs in the shot-making in-

¹The available data on this point will be discussed later.

FIG. 1—VACUUM SEPARATOR

²Theory and Practice of Ore Dressing. Wiard. p. 203 et. seq.

dustry. The superior rolling quality of the more perfectly rounded shot is taken advantage of in separating the perfect from the imperfect shot. The ungraded material is fed to a conical revolving surface at one point near the top of the cone. The more perfect shot will roll almost directly down to a discharge point along the edge of the cone which is almost directly below the feeding point, while the imperfect shot will roll more slowly and under the additional influence of the rotation of the conical surface report at points ahead of that where the perfect shot discharge.

Methods of making a series of gradings by fall of particles in currents of air, water or other fluids are described at a later point in the articles. This method of grading may also be employed to effect a splitting grading or separation. If air is used, large dust chambers will be required to settle the fine dust.

Grading by Air Separation

The Raymond air-separation apparatus is shown in Figs. 1 and 2. The material is fed in by an enclosed hopper at point 4. It is then drawn up between the inner and outer cones 7, the sectional area of the passage increasing toward the top or deflector 8. Between this point and the down-draft pipe 9 most of the coarse material will fall back and return to the comminuting device if one be provided below the feed point 4. The fine particles pass through the fan 6 and then through the collector 11 where the current of dust-laden air is given a centrifugal spin and drops the bulk of the finely divided material which can be collected at point 14. From the separator the air returns to point 4 by way of passage 3. It will be seen from this description that the device requires no dust chambers, for the air current is in a closed circuit and is used over and over again. While the air current returning to the feeding

FIG. 2—SECTIONAL VIEW OF VACUUM SEPARATOR

device may contain some fine material, this can be largely obviated by collection chambers of the proper size and regulation of the volume of air forced through the apparatus. Some regulation can be gotten through the wind gate A, Fig. 1. The Raymond apparatus is excellent for producing limited tonnages of impalpable powder. It is much used for preparing finely powdered drugs, pigments, graphite, etc.

Examples of Grading Incorrectly Termed "Classifying"

In the cyanide process for gold extraction and in a number of Western ore mills various forms of splitting grading devices are used to which the name classifier is wrongly given. The principal machines of this type are the Dorr, Akins and Federal-Esperanza, illustrated in Figs. 3, 4 and 5 respectively. In all these machines the material is fed in, mixed with a certain proportion of water, the amount of water being about six parts by

TABLE I		
	Akins	Dorr
Ratio water to ore	5.11	4.62
	Per Cent	Per Cent
Dry ore	16.38	17.64
Water	83.62	82.35
Tons, 24 Hours:		
Solids	92.76	76.20
Water	473.21	355.75

Sizing Tests

weight of water to one of ore. If the amount of water coming to the classifiers exceeds this ratio it is properly reduced in Western practice by suitable dewatering devices. In cyanide mills either the Dorr or Akins type is used. The Federal-Esperanza classifier has been used to some extent in Western concentrating mills. Table I illustrates the capacity and work of the three classifiers.

FIG. 3—DORR CLASSIFIER

FIG. 4—AKINS CLASSIFIER

FIG. 5—FEDERAL-ESPERANZA CLASSIFIER

The figures in the case of the Dorr and Akins are comparative, having been made in the same mill and on the same material.

The Dorr classifier, as a glance at the figures of this machine will show, uses a flight-pushing device. On the upward or push motion of the blades they dip into the sand, and on the return motion they are raised above the sand. The advancing means of the Akins is merely a double spiral which is open in the center to allow the water and slime to drain back. The Federal-Esperanza classifier is an endless belt to which are secured flights or vanes. The speed of the belt is from 15 ft. to 30 ft. per minute. The capacity of the individual flight is about 0.2 lb. per square inch of flight surface.

The power required for driving any of the machines does not exceed 0.01 to 0.02 hp. per ton of the dry material treated daily. Considering all the merits and demerits of the three types there is not much choice for excellence among them. If the Federal-Esperanza be in first-class condition with the conveyer chain properly drawn up so that it does not drag upon the bottom of the tank it should show the smallest power consumption of the three, followed by the Dorr and the Atkins; that is, the unit power consumption or consumption per ton of sand delivered. The wear of the conveyer chain from grit may, however, cause it to drag upon the bottom of the tank, materially increasing the power consumption.

More capacity can be gotten from the Federal-Esperanza type for the area of individual blade employed since the conveying operation is continuous. In the case of the Akins, capacity for any particular size of spiral is limited by the fact that if it is run at too great a number of revolutions it will merely slide through the sand and not push it ahead.

In the matter of attention to lubrication and general oversight to see that the machines are functioning properly, the Akins machine should require the least attention and the Dorr the most.

In the matter of wear and tear of the rakes or moving means, the Akins will report the most, and between the Dorr and Federal-Esperanza there will not be much to choose.

In the matter of starting up after flooding and with the tanks full of sand it will be found that the Akins may often be started without digging out, while with the other two kinds this operation will be necessary.

The Dorr machine is provided with a device for rais-

ing the rakes before shut-downs but if the machine is flooded unexpectedly this device will not be of much use.

In the matter of cleanness of products the Akins delivers the cleanest sand product and the Federal-Esperanza the most contaminated one, but there is not much to choose in this respect between the Akins and the Dorr. The Federal-Esperanza delivers the cleanest slime of the three, the Dorr being the poorest in this respect, though there is but little practical difference between the Dorr and Akins on this point.

The Federal-Esperanza type is the oldest of the three and before this device was put upon the market Western millmen had made use of similar forms. The principal improvement of the Federal-Esperanza design is the use of a sprocket wheel of sufficient diameter that its bearings may be carried well up above the water and grit in the tank below. In the manufacture of white

lead a classifier similar to the Federal-Esperanza had been in use for many years prior to the advent of this machine for separating the uncorroded portion of the buckles following the corroding and grinding operations.

The most interesting grading operations from a technical point of view occur in those industries where it is necessary to split a mass of material into three or more sizes. Grading of this kind can be done according to diameter or some other linear measure, or two linear measures; as, for example, in the grading of disks of varying size and thickness, by volume, by gravitation in fluids or by weight.

Necessity for Grading in Certain Industries

Some reasons for dividing a loose or broken mass of material into a number of sizes will be gathered from the following examples of the need of this operation in

FIG. 6—MERCURY FLOAT FOR GRADING BY WEIGHING

certain industries and uses. In the use of abrasives the aim is to produce a smooth or polished surface from a roughened one. To gain time the roughened surface must be reduced progressively by abrasive grains whose diameter is roughly proportional to the depth of the projections of the roughened surface. Quite evidently, while the abrasive grains are tearing or breaking away the projections of the surface, they are grooving the smoother portions to an amount proportional to the size

of grain used, though to a lesser degree. On this account, if the ultimate aim is a smooth or polished surface, the abrasive must be used in graded masses starting with a coarse size and ending with a fine.

For human and animal consumption salt is graded to obtain varying rates of solubility. For household use a quickly dissolving product is desired, while for layering meat the salt is desired in a condition where it will dissolve slowly. This requires that household salt be finely divided and yet not so finely powdered that it loses its crystalline character, and in a damp climate becomes caked in the receptacles for holding it. If fine salt were used for preserving meat it would quickly dissolve in the moisture of the flesh and run to waste permitting the entry of decaying agencies. A very coarse salt is consequently used for layering meats, intermediate sizes between this and the finest being used where greater rates of solubility are desired.

Coal is almost entirely graded because of the household demand that this material be so delivered. It is quite evident that the limited size of household fire-boxes will preclude the use of very large masses of coal. Again the limited height of household chimneys, or what is the same thing, the low velocity of the draft, forbids the use of much fines in the coal since it reduces the velocity of the gases in passage from the hotter part of the fire to the colder. On the other hand the surface exposed to the gases increases as the size of the particle decreases. For household purposes the best mean between long, crooked, narrow interstitial passages and area of pieces exposed to inflaming gases is somewhere between 1-in. and 4-in. pieces. If a quick fire is desired the best size will be somewhere near the lower limit of size. If it is desired that the fire burn to a bed of glowing coals and that the fire remain in this condition the greatest length of time, then a coal nearer to the larger size given will be selected.

The technology of grading by the use of screens and the means for obtaining volumetric grading will be left to the end of this section, and miscellaneous methods of grading will be taken up first, followed by modes of grading by fluids.

Miscellaneous Modes of Grading

U. S. Patent 1,080,088, Dec. 9, 1913, is for means of separating shrunken and discolored beans from perfect white beans. In this patent means are provided for bringing the beans singly to a position in front of a hinged spout. Means are provided for reflecting all the light from the beans on a selenium cell which consists of narrow strips of narrow strips joining broad brass plates forming portions of an electric circuit. If the hinged spout be supported by a magnet which is part of the selenium cell circuit, then when

FIG. 7A—SINE BLOCK FOR GRADING BY WEIGHING

the perfect beans pass through the apparatus, since the resistance of the circuit will be diminished from the greater light impinging on the cell, the spout will be raised to the highest point and if a receptacle is placed in the proper position below the edge of the spout, the perfect bean will fall into it. If receptacles are placed behind the first one a gradation can be obtained from perfect to dark, shrivelled beans. According to Adams, greenish yellow rays lower the resistance of selenium the most. The device described or something similar may offer a means of grading according to color, and perhaps of separating ore from gangue.

A silk-sorting machine is one for grading threads of silk according to thickness and winding them upon the proper bobbins. The proper bobbin is presented to the thread by the action of a lever which is governed by the thickness of the thread passing between gage-rollers.

Grading by weighing is only adapted to relatively large individual pieces. Each unit of such a device must have means for feeding the individual masses singly, and the interval of time must be sufficient to completely weigh and dispose of a piece before another passes over the grading means. The transportation element must not influence or interfere with the weighing element. A simple mode of obtaining grading by weighing would be to have a spout hinged at one end and supported by scale-beam connections at the other. Either of the devices shown in Figs. 6 and 7 would furnish the proper weight-opposing thrust Fig. 6 being a mercury float and Fig. 7 a sine curve weight-opposition, the spout hanging from or being supported by a strap or arm in contact with the curved surface which is at point A when the device is at the no-load position. With either of these devices means are provided for giving equal angular depressions of the spout for equal increased increments of weight. As with the selenium-cell device, if suitable receptacles be placed at the proper position below the hinged trough they will receive masses of equal weight.

Grading by Blowing

In grading by blowing, the air most commonly is introduced at the feeding point and from this point the air is expanded into a chamber of increasing cross section. The air may also be exhausted at the end of such a chamber, particularly if the very fine dust at the end of the chamber is to be forced through a dust collecting device. At regular intervals in the expansion chamber, gates are placed to receive the gradings which will, of course, be of a size inversely proportional to the cross section at any point. These gates are usually held to place by a lever and weight. When sufficient material has collected in the pocket above the gate to more than counterbalance it, the gate will open and permit the grading to discharge. Gates of this kind are, of course,

FIG. 7B—SINE BLOCK FOR GRADING BY WEIGHING

necessary to prevent the air from passing through the discharge passages, taking with it material which does not belong at this point.

Expansion chambers can be placed horizontally, on an inclination or vertically; in the last case consisting of a series of expansion chambers placed one above the other, the sizes increasing from top to bottom.

The vertical arrangement is the best from the theoretical point of view, but it has the disadvantage of requiring more head room than the other forms. With the vertical forms the air has the power to balance a grain of a particular size or weight, the balance being dependent upon the velocity, and this in turn upon the initial velocity created by the fan, and the area of the cross-section at the point of balance.

Grading by horizontal and inclined forms of chambers depends upon the transportive power of the air current, and the question as to whether a grain of a particular size will alight in the appropriate pocket depends not only on the transportive power of the current, but also the position of the grain in the current. If well above the discharge pocket into which it should discharge, it will fail to report in it and will be carried ahead. Also, if the grains which are reckoned too small to report in the pocket are in the current just above it, they will fall into it.

Air-grading is very little practiced to-day, for the settlement chambers required are very large as compared with settlement chambers for a heavier fluid such as water. If the material being graded permits of the use of water, this undoubtedly should be employed in preference to air. It is impossible to prevent strong cross-currents and eddies in the expansion chambers and this confuses the grading, making it quite markedly inferior.

A certain amount of fine dust is bound to cling to the walls at all points of the expansion chambers and this will contaminate the gradings.

There is no technology of this type of apparatus. In the vertical forms of apparatus, if the velocity of the air from point to point is known, as it can be, knowing the fan velocity discharge, it would be possible to calculate the size grain that the air current would balance. The pressures created by air velocities have only been calculated for large surfaces, and, as is well known, the smaller the surface the less does the unit pressure become.

In the inclined forms of chamber, the pressure of the air current is balanced against the inclined component of gravity less friction of the bottom of the chamber.

For horizontal expansion chambers of regular form, truncated pyramids or cones, the path of a particle in the feeding plane may be calculated theoretically from the following formula

$$y = \frac{x^2 A^2 g}{4 A_1^2 L V^2}$$

where A is the area of the small end of the chamber, A_1 the area of the large end, L the length of the chamber, V the velocity of the current in feet per second at the entry of the blast into the expansion chamber, and g the constant of acceleration.³ The axes of the curve are taken through the center of the particle just as it enters the expansion chamber, and, of course, values for y are negative and for x positive.

I have some information to the end that air-grading is used for separating chicken feathers into various sizes. In the dry process for mica, air-grading is still

used to some extent, but there are so many secrets in this industry that it is impossible to determine how the air-grading is done.

Grading by Projection

Some attempt has been made to grade material by the varying trajectory when thrown from the surface of an endless belt where it passes around a pulley. In this case, owing to the greater opposition of the air, the largest pieces should fall nearest to the pulley, with successively finer pieces as the distance from the pulley increases. If the particles are of different kinds of material and with different modes of fracturing, this mode of grading may offer means for separating the constituents by screening or other ways following the belt-grading. If the particles be of varying specific gravity the alighting position of particles of the same size will be modified to some extent by this difference, the heavier particle alighting somewhat closer to the pulley; but specific gravity differences will not affect the grading so much as differences in size or shape.

Professor C. F. Hirshfeld has experimented with this mode of grading in endeavoring to discover a means of separation for various constituents of a low-value ore which did not differ much from one another in point of specific gravity. It was found that very high belt-speed was necessary and this required that the apparatus be massive and have good foundations. Another difficulty encountered was with the differential crawl of the material on the belt under the high speed necessary. This was overcome by having two belts in contact with one another, both running in the same direction and with the same speed, the material being conveyed by the lower one and slippage being prevented by the upper. Both belts were run horizontally.

True Classification in Rising Currents of Water

Grading which is done by an uprising current of water or other liquid is called classification. In the ore-milling industry this mode of grading has some advantages over screens or other modes of grading in preparing material for certain kinds of separating machines. The technology of grading in rising currents is discussed at length in the text books on ore-dressing.⁴

Outside of ore-milling, grading by rising currents does not receive any extended use, for the work done is not sufficiently sharp for the majority of grading problems. The characteristic of any grading made by classification is the presence of grains whose size is well defined as to the upper limit, but the lower limit can scarcely be said to be defined at all. The majority of the grains are of sizes nearer to the upper limit than the lower; but in every classification there are grains of all sizes, from the largest which are rejected by the current in the grading next above any particular one in consideration, down to the very finest. When particles fall in water, beyond a very brief moment of acceleration the rate of fall is uniform, and depends upon the size of the grain—large grains falling faster than small—and on the specific gravity the greater the specific gravity the greater the rate of fall.

Formulas for rate of fall and their variation from experimental results will be found discussed at length in the authority which has been given. Theoretically, when the rising current just balances the velocity of any particular size and kind of grain, all particles of larger size should fall and smaller ones rise. In practice, the friction of the current on the sides of the enclosing hydraulic chamber, the deflections of the current caused

³The retardation in fall by air friction has been neglected and since the gradation of size depends on the large grains falling faster, a factor depending upon size would have to be applied to the formula to obtain the actual path.

⁴'Richards' Ore Dressing will be found to be the best authority to consult, the author having been for a long period an authority on this branch of the subject.

by the falling grains and certain interstitial actions which occur between the larger grains, cause downward forces tending to carry down and deliver with a particular grading small particles which do not belong to it.

In addition to grading by rising currents there is the form of water classification which is practiced to some extent by direct settlement for varying periods of time. In the abrasive industry there are classification grades made by the settlement of the material in cones of increasing diameter. Following the grading done in this way, a barrel is filled with the overflow of the largest classification cone and the material in the barrel is allowed to settle for a definite length of time. Material which has failed to settle in this period is siphoned off into a second barrel where it is allowed to settle for a greater length of time, when the siphoning operation is again undertaken, and so on, the successive operations yielding any desired number of grades and of any desired fineness.

Methods of Grading Very Fine Materials

For grading analyses below 200-mesh, a settlement-and-siphon method is used to some extent, the results being reported as such and such percentages for such and such times.

A better mode of carrying the sizing test below the limit of screens is to take a small portion of the minus 200-mesh product and measure it under the microscope, the measuring device being a carefully ruled grid on a glass plate holding the particle to be measured.

The most generally accepted set of testing screens have the apertures diminishing in size by reducing the area of the aperture a half from screen to screen. If the glass plate be engraved with squares which diminish in the same way beginning with half the area of the 200-mesh screen, the standard width of opening of which is 0.0029 in., a count may be made of the grains which are larger than the different size squares, the various groups of oversized grains being successively removed from the sample after measuring. This method is limited by the magnification of the microscope and the skill of the investigator.

In calculating the weight of a particular grading by this method, the average linear dimension of the squares (half the sum of the side of square on which the grain is being tested and the side of the next largest square) is cubed and this factor multiplied by number of grains to obtain weight and percentage by weight. This mode of computation is, of course, only approximate and subject to much error.

The direct weighing of the particles entails great care and skill, and the difficulties of obtaining the weights and percentages by direct weighing increases as the size diminishes. Increased accuracy might result if the microscopical apparatus were mounted with a gage for taking the depth of the grain.

(To be continued)

Denver, Col.

Steel Plant to Have Entire Electrical Equipment.—The Inland Steel Company has placed an order with the Westinghouse Electric & Manufacturing Company, of East Pittsburgh, for the complete electrical equipment of its new plant at Indiana Harbor, Ind. The order represents an expenditure of over one million dollars and when completed the company will have what is said to be the largest electrically-driven steel plant in the world.

Aluminum in 1915.—The production of aluminum in 1915 is estimated by several authorities to be close to 80,000,000 lb. This is a record of achievement and compares with production in 1914 estimated at 45,000,000 lb.

Blast Furnace Smelting of Cyanide Precipitate

BY REGIS CHAUVENET

It is not necessary to review all of the methods which have been used or proposed for the treatment of the so-called cyanide "precipitate." These methods, to use a rather Hibernian expression include the case where there is no precipitate to treat, as for example the re-gaining of the gold without the use of either zinc or carbon.

Originally, the most obvious method was the first attempted. Nothing was simpler, on paper, than the solution of the zinc and all other impurities in some appropriate solvent, leaving the gold behind. It was discovered before long that there were many cases in which this was quite impracticable; and, naturally, they were so in the proportion in which the impurities were themselves insoluble or difficultly soluble in the menstruum.

Nitric acid is out of the question to begin with, on account of its expense. Take for example, copper, whose average equation of solution is:

We destroy 2 $\frac{3}{4}$ lb. of actual nitric acid for each pound of metal, approximately the same for zinc, though considerably less for lead. Indeed, the cases quite other than the one under consideration, in which nitric acid has been proposed, and abandoned on account of its cost, are numerous in the annals of hydro-metallurgy.

As for sulphuric acid, it will not dissolve lead except under "impossible" conditions. It takes up copper only by application of a mixture of air and steam. This has been used in the purification of silver, but as the question is almost always complicated by the presence of other impurities, sulphuric acid for the removal of copper at the same time with the zinc, is of a class of problems more curious than practical.

However, as is well known, sulphuric acid has been used in those cases where the total copper *plus* total lead are so low that the precipitate is substantially nothing but gold and zinc.

Fire Methods of Refining Precipitate

Other curious methods have been proposed, some of them heralded as the "long-looked-for-come-at-last." This brief discussion of wet treatments of the precipitate is intended merely to introduce the subject of fluxing, i.e., to indicate that there are cases in which some form of dry treatment, more or less approximating actual smelting operations, is imperative. There remains, to be sure, electrolytic separation, but here again conditions often prohibit.

We are reduced to three furnace methods:

- (1) Direct cupellation.
- (2) Reverberatory hearth.
- (3) Blast-furnace.

For purposes of this discussion the first method is rejected on account of high copper.

We must here quote rather extensively from the long and highly informative articles by J. W. Hutchinson, on the Goldfield Consolidated mill, where the operations to be presently described were initiated. We condense the description of the original method of smelting, but it is necessary to indicate the difficulties of the earlier trials in order to appreciate the improvement introduced by the full smelting method.

The melting-room as originally designed, contained a double-muffle drying-furnace and four Faber du Faur tilting furnaces for treating the precipitate. The proc-

¹Min. & Sci. Press, May-June, 1911. Reproduced in "Cyanide Practice, 1910-1913," Von Bernewitz.

ess consisted of nitre-roasting the precipitate, with subsequent melting in the tilting furnaces. Bullion from this method averaged 250 fine in gold and silver.

Later, acid-treating tanks were put in which materially reduced the amount of precipitate to be melted, and by addition of pyritic concentrate, enough copper and lead were converted to matte to raise the grade of the bullion to 425 gold and silver. (The analysis here introduced is omitted, but the bullion shows over 40 per cent of copper, 13 per cent of lead and $3\frac{1}{2}$ per cent of zinc.)

No wonder that, to quote again from the article, "The process was decidedly unsatisfactory." Much work was done to ascertain whether some wet method could not be adopted. Electrolytic parting was suggested and abandoned. Another method which included matting away of the copper, gave a lead bullion high in gold and silver.

It had been about decided to try reverberatory smelting, first briquetting the precipitate with litharge and fluxing on a reverberatory hearth. Mr. Hutchinson here gives Mr. Henry Hansen of Blair, Nev., credit for the suggestion of blast-furnace treatment. It had been tried on a small scale at the Pittsburgh Silver Peak Company.

Blast-Furnace Smelting of Cupriferous Precipitate

The new departure consists in nothing less than the actual smelting of the precipitate on a lead basis, in a small furnace constructed in miniature exactly like a lead-smelting furnace. "Smelting precipitate containing 40 per cent copper on a lead basis did not sound very attractive as blast-furnace work at first," but it was soon found that it could be efficiently done.

Briquettes were made consisting of:

Dry precipitate	100 parts
Litharge	100 to 125 parts
Blanket concentrate	60 to 75 parts

This "concentrate" held 35 per cent silica and 30 per cent of sulphur. Subsequently the proportion of litharge used in the briquettes was made still higher.

The precipitates of several years had the following average percentage analysis:

	1911	1910	1909
Au	21.50	8.75	13.43
Ag	3.00	1.14	2.13
Cu	39.80	21.59	22.85
Pb	4.50	28.58	6.86
Zn	15.50	12.57	32.50

There is variation enough here to bring much "grief" to the experimenters. Nevertheless success eventually crowned their efforts.

It is evident that if the precipitate is to be treated in a blast furnace "on a lead basis," there may be two cases, viz.: matte or no matte. With high copper the only practicable scheme is the formation of a matte, and this will perhaps inevitably entrain both lead and zinc. In the absence of copper this necessity disappears. Hence came the addition of concentrate to the charge, which in the case of the high copper precipitate was left raw for the utilization of its sulphur, but when copper was practically absent it was added more for the sake of its silica (for slag formation) and its incidental value. In this case roasted concentrate was used.

In both cases the addition of iron oxide is almost a *sine qua non*, since we are to depend mainly upon the reduction of the lead for the collection of the gold and silver, and the carrying of the zinc into a slag, which would hardly possess the requisite fluidity unless high in iron.

Effect of Zinc in Slags

The composition of a slag which is to carry zinc oxide, is too well known to require much discussion. It is true

that we are not trying to dictate composition, but rather method of computation of this slag, but some consideration of its essential qualities cannot be wholly omitted. Lime and zinc oxide seem to be natural enemies, so far as slagging together is concerned. It has often been given as a rule, that when lime rises into the twenties in a slag, zinc acts more and more as a stiffener, and it is said that when lime reaches 28 per cent, zinc oxide refuses to enter the slag at all. While we are not responsible for these figures, there is no doubt that zinc cannot be slagged off in smelting unless high iron is present. Iron is added in such cases to such an extent as to lessen materially the total percentage of silica.

The blast furnaces adopted at Goldfield are of the cylindrical type, 20 in. in diameter at the tuyere line, with riveted steel jackets. In blowing in the wood fire is maintained until crucible and lead-well are cherry red. Coke is added and the fire urged to white heat. Five hundred pounds of lead is fed in to fill the crucible. Blank charges of coke and slag are fed until the furnace is half full. Then comes the regular charge, consisting of:

Briquettes	100
Old slag	40
Borax	10
Cupel bottoms	51
Iron (oxidized)	2
Coke	25

So far, the old practice. The lead bullion contained under this method approximately 20 per cent gold and silver, and 1 per cent copper. The matte from these runs contained average of 20 per cent lead, 50 oz. gold and 200 oz. silver per ton. This accumulates until sufficient matte is on hand to be separately run.

TABLE I

Analyses of all the constituents of the charges, except iron oxide which is nearly pure Fe_2O_3 obtained by dead-roasting pyrite. Gold and silver contents of Consolidated and Aurora precipitates are given in ounces per ton; gold value of raw concentrate in dollars. All other figures are percentages.

	Consolidated Ppt.	Aurora Ppt.	Raw Concentrate	Roasted Concentrate	Selby Slag	Remarks
Au	3470	2578	\$50			
Ag	808	2229				
Cu	22.0	0.2	0.5	0.6		
Zn	22.0	40.8				{ 40.8 called
Fe		0.5	20.0	22.2	40.0	{ 41 in problem
				(40 FeO)	(51.4 FeO)	
CaO	5.5	7.2			20.0	
SiO ₂		11.6	50.0	54.6	30.0	{ 55 in problem
S			19.0	1.0		{ 54.6 called

Mr. Eugene G. Snedaker has kindly furnished us with analyses of the various products which enter into the problem. As to the slag produced, we are not able to pronounce upon it, as it shows a summation of less than 77 per cent, viz.:

	Per Cent
Insoluble	24.8
FeO	26.3
CaO	5.5
ZnO	12.3
Pb	6.5
Cu	1.3

"Soluble silicates and borates undetermined; gold, 1.2 oz. per ton."

This, inferentially, leaves us with the astonishing proposition that $22\frac{1}{2}$ per cent of the slag consisted of bases other than those named. Here, however, we drop discussion of the practice, as it is mainly our intention to explain the computation of a rational flux addition to the briquettes.

Turning now to the analyses of precipitates, concentrates and Selby slag given in Table I, it appears that we have to consider both high and low copper, also both raw and roasted concentrate. As it is obvious that one of these cases demands a matte and the other none, we take them up as two separate problems.

Problem I. No Matte Formed in Smelting

Assuming then, that in any given charge or campaign we are to use but one of the given precipitates, we start with the Aurora.

Theory calls for the addition of about 150 lb. of litharge to 100 lb. of precipitate, to supply oxygen for the reaction:

In 100 lb. of precipitate (zinc = 41 per cent) the atomic weight proportion is:

$$65 : 16 = 41 : 10.10$$

And for litharge:

$$223 : 16 = 150 : 10.76$$

The margin is small, being in fact 10.76 minus 10.10, or 2/3 lb. for oxygen. Probably the addition of a little more litharge would become the practice.

Leave out of all account, in slag calculation, the gold and silver. The reduced lead, *plus* that with which you start in the crucible should take care of the precious metals. Some lead will in all probability get into the slag. With it, possibly some gold and silver. As the slag is to be re-treated this is not prohibitory.

We now use the "representative" method of slag computation already illustrated several times in this journal.²

We enter our calculation with 51 lb. of zinc and 7 lb. of lime, each of these from the 100 lb. of Aurora precipitate. We are figuring for a slag, and we may leave matte out of the reckoning, as we have but 1 per cent of sulphur in the roasted concentrate. This trifle of matte will be drawn off with the slag and will go into the retreatment of the latter.

What slag shall we figure for? I adopt the purely arbitrary figures $\text{SiO}_2 = 30$ per cent, $\text{FeO} = 50$ per cent and $\text{ZnO} = 20$ per cent. The lime is to be *included* in the figure for zinc oxide. Iron oxide (Fe_2O_3) has to be provided as flux, and it appears from the records of the company that a roasted pyrite furnished this essential constituent of the charge.

As usual assume 100 lb. as basis for your calculation, i.e., 100 lb. of precipitate. Call your concentrate 100x, and your iron oxide 100y.

Get expressions for total silica, FeO and ZnO (include CaO in the latter).

Remember that the Fe_2O_3 reduces in slagging to FeO, whose weight is exactly 90 per cent of the higher oxide. Expressions for all the constituents will be as follows:

	SiO_2	ZnO	FeO
From precipitate	12	58 (c)	... (a)
From concentrate	55x	..	40x (b)
From Fe_2O_3	..	..	90y
Totals	12 + 55x	58	40x + 90y

(a) Neglect the 0.5 per cent iron in the precipitate. (b) The 32.2 per cent Fe in the concentrate is equivalent to 40 per cent FeO. (c) The 41 per cent Zn is equivalent to 51 per cent ZnO; this added to the 7 per cent CaO makes 58 per cent of the two oxides.

Now by the slag conditions of the problem ($\text{SiO}_2 = 30$, $\text{FeO} = 50$ and $\text{ZnO} = 20$), we have $5 \times \text{SiO}_2 = 3 \times \text{FeO}$, that is:

$$60 + 275x = 120x + 270y \quad (1)$$

Also, $2 \times \text{SiO}_2 = 3 \times \text{ZnO}$, that is:

$$24 + 110x = 174 \quad (2)$$

These two equations which are very quickly solved, give us $x = 1.3636$ and $y = 1.005$ or $100x = 136.36$ and $100y = 100.5$. That is: for each 100 lb. of precipitate add 136.36 lb. concentrate and 100.5 lb. of iron oxide.

²Calculation of Furnace Charges, Regis Chauvenet, this journal, January, February, March, April and June, 1912.

PROOF.—Take the quantities indicated, and calculate from the analyses the weights of each constituent added. If these come out in the proportions required, i.e., 30 : 50 : 20, the proof is perfect.

	SiO_2	FeO	ZnO
Precipitate	12	..	58
Concentrate	75	54.55	..
Iron oxide	..	90.45	..
	87	145.00	58

The sum is 290 lb. slag, and calculating the percentage of each constituent, we find that:

$$87 : 145 : 58 = 30 : 50 : 20$$

exactly as required by conditions.

The slag then, irrespective of the old slag addition to be presently mentioned, will have the composition, $\text{SiO}_2 = 30$ per cent, $\text{FeO} = 50$ per cent and $\text{ZnO} + \text{CaO} = 20$ per cent.

Function of Old Slag in Charge

In all smelting operations of this general description, old slag is added to each charge, to facilitate melting. In the description of the former practice it is stated that the old slag from the operation itself was added, though it became so "zinky" that it had to be rejected after a while. Instead of this addition, "Selby" slag is substituted. It is not usual, nor is it necessary, to work the analyses of this addition into the general computation. The old slag, because it does not have to go through the formation period, aids the melting of the charge. Its composition as shown ($\text{SiO}_2 = 30$ per cent, $\text{FeO} = 50$ per cent (about), and $\text{CaO} = 20$ per cent), is singularly near the desired final outcome. This addition of a standard slag from lead practice, is greatly to be preferred to the return of the zinky slag from the smelting of the precipitate. Incidentally, composition is bettered, because of the lowering of the percentage of zinc. It will always be a problem more or less difficult to obtain a slag which, in carrying off all of the zinc, will at the same time be fluid enough for easy handling.

It was then, not without a realization of these troublesome elements that the management adopted "Selby" slag as the regular addition to their charge.

In the computation to follow all bases other than FeO are set at 20 per cent, zinc oxide being the chief one.

Here let us say, once for all, that we wish to illustrate a method of computation, and are not dictating the composition of a slag obtained under conditions unfamiliar to us. Whether the particular proportions are the best does not cut much figure, since the method is perfectly general. Thus, if a slag proves to be too pasty because it is too zinky, lower its zinc contents and recompute the charge. In short the *method* is mathematical, not physical. We apply our knowledge of slags, of course. We remember that high lime and zinc are incompatible, and that multiplicity of bases helps fluidity, and we bring to our aid whatever local experience has indicated. This experience having given us a preferential composition, all our method does for us is to give an easy solution for compounding the charge for production of the desired result.

Problem II: Matte Formed in Smelting

We now take up the "Consolidated" precipitate, which, being high in copper, is to be smelted with raw sulphide concentrate.

We must first "take out" the matte from the raw concentrate, i.e., calculate out its iron against its sulphur. The iron is 20 per cent in the raw concentrate. Apportion it on the formula FeS to the sulphur:

$$56 : 32 = 20 : 11.4$$

$$\text{Fe} \quad \text{S} \quad \text{Fe} \quad \text{S}$$

That is, sulphur required for iron in matte is 11.4 per cent. We have 19 per cent sulphur in the concentrate, which minus the 11.4 per cent required as above leaves us 7.6 per cent which is to be adjusted to the copper of the precipitate. This sulphur may be adjusted thus; the formula of the copper sulphide in the matte is assumed as Cu_2S , which contains practically exactly four times as much copper as sulphur. That is, in 100 lb. precipitate we must add available sulphur weighing one-fourth of our copper content of 22 lb. One-fourth of 22 is 5.5. We have then simply to answer the question, "How many pounds of concentrate with 7.6 per cent available sulphur will yield 5.5 lb. of same?" That is, merely,

$$7.6 : 100 = 5.5 : 72.4.$$

That is, 72.4 lb. of the raw concentrate will supply sulphur enough both for its own iron and for the 22 per cent copper of the precipitate.

Since we have 50 per cent silica in the raw concentrate, 72.4 lb. contain 36.2 lb. silica.

In 100 lb. precipitate we have

22	zinc	=	27.4	ZnO
5.5	CaO	=	5.5	CaO
Say..... 33 lb. base				

We want, say 50 per cent FeO in the slag. Now since we have 36 lb. SiO_2 and 33 lb. base, the two making 69 lb., the other half of the slag, FeO, must also be 69 lb. This weight of FeO will be yielded by 76.6 lb. of the ferric oxide, Fe_2O_3 .

By pounds the slag will be:

SiO_2		36
Base		33
FeO		69
Total		138 lb.

By percentage composition this reduces to:

SiO_2		26 per cent
Base		24 per cent
FeO		50 per cent

The charge then, irrespective of coke and "Selby" slag, will be:

Precipitate		100.0 lb.
Concentrate		72.4 lb.
Fe_2O_3		76.6 lb.

This method of computation assumes that we must apportion the iron in the concentrate to its sulphur, and then compute the whole of the added iron oxide into slag. This is as good a way as any, but, in fact, there are half a dozen ways, more or less conventional, of adjusting the bases to sulphur and silica.

Impossible to Form Both Slag and Matte of Assigned Composition

In review it must be noted that we have here conditions whose simultaneous fulfillment is impossible. For it will not be possible to compose a charge so that we shall have at once a slag and a matte of assigned composition. In other words we have two incompatible conditions, which could be simultaneously satisfied only by a fairly miraculous coincidence.

Having, however, secured an approximation to the desired slag, it would be easy to get the exact requirement, provided we had perfectly pure material, i.e., material containing only silica, or only base. As to what the ideal slag for the operation would be, could be determined only by experience, and a good deal of it.

Let us exemplify by two assumptions: (1) we have the "Selby" slag, and (2) we have pure SiO_2 and pure Fe_2O_3 . Now we can never get a precise solution by the addition of another slag, for the addition of one element enforces the addition of others in set ratio, i.e., only by a miracle could we get the ideal.

With separate pure material on the other hand we can always secure any desired slag. This we shall illustrate in conclusion of the article. We should add that as a mathematical principle, we may always secure any required slag provided there are but three constituents in the aggregate composition.

First. Suppose we use "Selby" slag to assist in slag formation. This, by the way, is supposing what is actually done in every charge.

As sent to us the analysis figures out 101 per cent, so we knock off 1 per cent and call the "Selby" slag:

SiO_2		30 per cent
FeO		50 per cent
Base		20 per cent
Total		100 per cent

Add 100 lb. of this slag to our already deduced charge, we shall have:

SiO_2	=	36 + 30	=	66 lb.
Base	=	33 + 20	=	53 lb.
FeO	=	69 + 50	=	119 lb.
Total				238 lb.

The composition by percentage is very easily figured out, giving:

SiO_2		27.7 per cent
Base		22.3 per cent
FeO		50.0 per cent
Total		100.0 per cent

We see that we have not made any great change in the composition. The "Selby" assists in formation but not in proportions, i.e., not materially.

It is quite otherwise when we come to additions of Fe_2O_3 and SiO_2 . Take the original charge and add as shown. We are trying to secure as nearly as possible the original requirement, and to do so we add *such weights* of SiO_2 and FeO as to bring their totals to the ratio of three to five. This explains the apparently arbitrary assumption of 24 and 31 as the additions of SiO_2 and FeO. To get 31 lb. FeO we add 34.4 lb. Fe_2O_3 .

Pounds in slag:

SiO_2	36 + 24 added making	60 SiO_2
Base	33 + 0 added making	33 Base
FeO	69 + 31 added making	100 FeO

Reduce the above mixture to analysis:

SiO_2		31.1 per cent
Base		17.1 per cent
FeO		51.8 per cent
Total		100.0 per cent

We recognize this at once as a fusible slag. It might be slightly improved by dropping silica a trifle. However, with its high iron and its bases (zinc and lime) cut down to a total of 17 we shall hardly "freeze."

Various changes may be introduced into the composition by prior calculation; the possible variants being infinite, we leave them to the student's devices. We shall give a single case. Suppose that to each 100-lb. slag (26:50:24) we are to add SiO_2 and Fe_2O_3 so as to bring it to (30:50:20). We may do so without equation, thus: The base equals 24 per cent, which by the proposed change is to become 20 per cent. Then the weight must be made 120 of which 60 (50 per cent) must be FeO; therefore, add 10 FeO (11.1 Fe_2O_3) and 10 SiO_2 . Then we have:

SiO_2	=	36
FeO	=	60
Base	=	24
Total		120

and the required percentages are obtained, i.e., 30:50:20. Similarly any desired change can be readily made.

Recent Chemical and Metallurgical Patents

Electric Furnaces

Electric Furnace.—A pinch furnace containing several compartments is patented by CARL HERING of Philadelphia, Pa. The principle of the pinch furnace was described by Dr. Hering in this journal, Vol. IX, 1911, pages 277 and 371. The present furnace is designed primarily for melting material of low resistance, such as copper, silver, gold, or alloys. The compartments are connected with each other by channels and a circulation through the

compartments is created by the pinch effect. A two-compartment furnace is shown in plan and cross-section in Fig. 1. The cross-section is taken on the line XX of the plan view. The furnace proper, of refractory material, is shown at W. The two compartments, H, H', are filled with the material to be melted. The electrodes EE' are connected to the bottom of the compartments in contact with the molten material as shown. The channels R'R' meet at P and communicate with the common pouring spout S. By using more compartments, such as three or five, or more, three-phase alternating currents may be used. The advantages claimed for this type of furnace are that it permits of the use of relatively higher voltages, lessening the electrode losses, and also permits of the use of different slags in the different compartments with correspondingly different refractory linings. In refining steel, an acid slag may be used in one compartment, while a basic slag is used in another, thus avoiding the need of changing slags. By using a number of compartments, cold metal or raw material can be introduced in one compartment for melting, while another compartment may be used for refining the slag or other treatment, thus making a continuous process. The resistor channels may be made of other shapes, such as conical for the purpose of making the flow stronger in one direction than in another (1,162,773, Dec. 7, 1915).

Electric Furnace.—A patent of ALEX DOW of Detroit, Mich., refers to electric furnaces using a granular resistor, such as carbon, as heating element, the object to be treated being placed above and heated by radiation from below. As the radiating surface of the resistor assumes a temperature slightly lower than the rest of the resistor, the current is caused to be deflected downward on account of the increase in resistivity of carbon with decrease of temperature. To overcome this defect in furnaces of this type, Mr. Dow places a series of bars of magnetic material (iron) below the granular resistor and at right angles to the direction of the current. These bars become magnetized and deflect the current upward toward the working zone of the furnace where the heat is needed (1,164,634, Nov. 23, 1915).

Electric Furnace for Producing Aluminium Nitrides.—A furnace for manufacturing aluminium nitride from bauxite and coal based on the original intermittent electric furnace process of Thomas L. Wilson, patented in England in 1895, is patented by GEORGE COUTAGNE of Lyon, France. Several modifications have been made in lower electrode and in the furnace casing. A cross-section of the furnace is shown in Fig. 2. The upper electrode H is a movable solid cylinder. The lower electrode is made of a large tube A of agglomerated coal. Between A and the shell of the furnace refractory material C is placed. Within A is a column of coke B. The nitrogen-containing gas, such as generator gas, is introduced through D into the annular space E under pressure, and is forced up through the furnace. No refractory lining is used on the shell above C, and all openings K at the top are made gas tight. In starting the furnace the upper electrode is lowered until it touches B. The coke is allowed to heat up for

FIG. 1—PINCH FURNACE

FIG. 2—ALUMINIUM NITRIDE FURNACE

awhile, then the mixture of bauxite and coal is gradually added through openings K, and the flow of generator gas is started. The work of the current is localized toward the center of the furnace and the outer portions of the charge adjacent the iron casing will not conduct the current so much. This permits the use of the unlined casing above mentioned. An operation lasts several days, and when finished the whole furnace is filled. The aluminium nitride is formed in a cake at the center of the furnace when cooled down, and is surrounded by an agglomerated mass of coal and bauxite at the periphery. The nitride is subjected to a high temperature during the operation, and it is stated that the retrogression studied by Fraenkel (*Zeit. für Electrochemie*, April 15, 1913) at 1500-1600 deg. does not take place (1,158,899, Nov. 2, 1915).

Electric Furnace.—An electric furnace which utilizes the heating effect of eddy currents is patented by Sigmund Guggenheim of Berlin-Wilmersdorf, Germany. Three-phase currents are used, which is claimed to make the melting operation more economical by providing a greater concentration of magnetic lines in the body to be heated. The furnace consists of a receptacle containing the material to be heated, placed in the air gap between the poles of three magnets. When these magnets are wound so that their current supply is in the same sense, a large proportion of the magnetic lines of force will not pass entirely through the material to be heated, but will be diverted from one pole to the next adjacent one. If, however, the winding

of the middle magnet be made such that the current is in the opposite sense to the other two, then a much larger number of lines of magnetic flux will go through the material to be heated. This unequal displacement of the magnetic phases is the feature of the furnace. (1,157,691, Oct. 26, 1915.)

Cementing Carbon Articles and Electrodes.—In baking carbon articles a porous product is apt to result due to the escape of volatile matter while baking. This is objectionable as it raises the resistance and in the case of carbon anodes the deterioration is hastened. A process for making the articles more dense by simultaneous heating and compression is patented by JOHN W. BROWN of Lakewood, Ohio, (assigned to National Carbon Company, Cleveland, Ohio). The articles are first impregnated with a tarry binder and then placed between plates for compressing and each end connected to electric terminals. An average current density of 1000 amp. per square inch is used. After the articles have heated up the material becomes semi-plastic and flows, cementing the particles together. The pressure does not have to be applied at the start but may be omitted until the material becomes heated. In the apparatus described the pressure is applied by a hand wheel. (1,158,171, Oct. 26, 1915.)

Electrolytic Processes

Diaphragm for Alkali Chloride Electrolysis.—In order to make it possible to use high currents with a vertical diaphragm cell a patent of ADOLF CLEMM of Mannheim, Germany, proposes to use a compound diaphragm, i.e. a diaphragm made up on one side of a substance which is not attacked by chlorine and on the other side of a substance not attacked by alkali hydroxide. The construction of this diaphragm is shown in Fig. 3. A powdered material *b*, such as barium sulphate, not attacked by chlorine, hydrochloric acid, or alkali, is supported on the cathode side by a material *a*, such as asbestos, while strips *c*, of glass, ebonite, or stoneware are arranged on the anode side. The diaphragm is claimed to be very durable. (1,160,847, Nov. 16, 1915.)

Acetic Acid from Acetylene by Electrolysis.—A process for producing acetic acid from acetylene by electrolysis is patented by CHRISTIAN HANSEN and ANTON WEINDEL of Leverkusen, Germany (assigned to Synthetic Patents Company, Inc., New York City). "The anode space of an electrolyzing chamber provided with a diaphragm of clay and an anode of platinum is charged with sulphuric acid (30 per cent) and 1 to 2 per cent of mercuric oxide, calculated according to the weight of the anodic liquid, while the cathode formed of lead or copper is also immersed in sulphuric acid (30 per cent). Acetylene is then introduced into the anode space, allowing the electric current to pass through and stirring at the same time. In this process 48.5 parts of acetylene are used every hour for every 100 amp. of current. The tension of the bath at a current density of 0.25 to 0.75 amp. per square decimeter of anode surface is 3 to 4.5 volts, and the temperature of the electrolyte is kept at 30-40 deg. C. A good yield of acetic acid is obtained" (1,159,376, Nov. 9, 1915).

Electro-Osmosis

Electro-Osmotic Filter Press.—In removing water from peat, clay, kaolin and like substances, consider-

able pressure has been heretofore required in filter presses as the fineness of the solid particles in suspension decreased, but for colloidal matter these presses could not be used. A press in which osmosis is taken advantage of has been patented by BOTHO SCHWERN of Frankfurt-on-the-Main, Germany, (assigned to Gesellschaft für Elektro-Osmose M. B. H. of the same place). In this press the material to be treated is run into the filter press chamber as into any ordinary press. But the two walls which hold this material are made electrodes of opposite polarity. They are perforated and a filter cloth placed over them. By using electricity and pressure, combined the water may then be extracted running into the adjacent empty chambers and passing out. The form of the press is about the same as an ordinary filter press. The electrodes are made of hard lead and the pressure required will be very slight, and under certain conditions suction may be used. In removing water from peat, clay or chalk by this method it has been found that ferric hydroxide separates out at the electrode toward which the water migrates, usually the cathode, and gradually chokes the press. This may be overcome by reversing the current occasionally. (1,156,715, Oct. 12, 1915.)

Aluminium

Treating Aluminium Scrap.—A process of treating aluminium screenings, dross or slag from aluminium casting operations for the recovery of aluminium and other metals is patented by JAMES WRIGHT LAWRIE of Aurora, Ill. The scrap which may contain iron, copper, zinc or other metals is screened through a fine screen and slowly fed into a closed tank provided with stirring mechanism, outlets for gases, and means of applying external heat and pressure. The tank contains a caustic soda solution, which dissolves the aluminium and alumina. Alumina has a negative heat of solution in caustic soda, but the necessary heat is furnished by the aluminium and other substances in the material and by applying external heat. A charge consists of 3000 lb. of material and 2500 lb. of caustic soda in 5000 lb. of water constitutes the solvent. The material is fed in fast enough to furnish enough heat for solution and not too fast to cause foaming or violent boiling over. The external heat is applied at first after the heat of the reaction has been sufficiently used up, with at first only a slight pressure on the solution. Later the pressure is elevated and the solution of the alumina continued. The charge is filtered after dissolving and the residue treated for the recovery of zinc, copper and other metals. The aluminate solution is precipitated as hydrate of alumina, filtered and the solution used again. (1,156,606, Oct. 12, 1915.)

Boron

Stable Boron Nitride.—The boron nitride produced according to most processes is not chemically stable, being slowly decomposed by hot water, forming boric anhydride and ammonia, and is also liable to oxidation. A process for making a stable product is patented by George Weintraub of Lynn, Mass., (assigned to General Electric Company). He discovered that when unstable boron nitride is heated to a temperature of 2000 deg. C. or higher, a stable product results which can be heated in boiling water without any noticeable decomposition, and is less easily oxidized. The process may be carried out in an electric resistance furnace, and any unstable boron nitride may be used as a raw material. About 20 per cent of a boron compound such as borax or boric anhydride is added to prevent any oxidation of the boron nitride. The heating is continued until no more fumes are given off. The time is comparatively

FIG. 3—COMPOUND DIAPHRAGM

short depending on the quantity used. (1,157,271, Oct. 19, 1915.)

Alloys

Hard Alloys of Lead and Alkaline Earth Metals.—In a number of patents granted to FRANCIS C. FRARY of Minneapolis, and STERLING N. TEMPLE of St. Paul, Minn., the inventors describe alloys of lead with calcium, magnesium, strontium or barium, or all together, and with or without small quantities of copper and aluminium. It is claimed for these alloys that they excel antimonial lead in hardness and toughness, and that they may be successfully used for such purposes as type metal, or wherever an alloy is desired for molding purposes. As the metals added to the lead are used in small quantities compared with the amount of antimony used in hard lead, the new alloys are proportionately less expensive than antimony lead, particularly under conditions when antimony is at an excessively high price. (1,158,671-2-3-4-5, Nov. 2, 1915.)

Iron and Steel

Charge-Car for Sintering Machine.—In sintering fine ore in pans it has been customary heretofore to provide a removable cover with burner mechanism, but without mechanical means for quickly and easily handling the cover; also the charging and leveling of the pans has frequently been done manually. According to the details of a patented charging car designed by Messrs. FRANK D. CARNEY and RICHARD V. MCKAY, of Steelton, Pa., mechanism is provided for raising or lowering the pan cover when the car has been run over the pan. The cover is provided with a drop bottom which carries a sufficient charge to fill the pan when dumped, and the bottom also acts as a leveling means for leveling the charge. The car carries an electric motor which actuates the mechanism as well as tanks for oil and compressed air and means for supplying the air tank with air at suitable pressure. These tanks supply fuel and air to the burner, which is on a level with the dumping bottom. A feature of the device is the delivery to the pan of a charge of uniform compactness, resulting in a reduction of the amount of fine, unsintered material remaining after the operation. (1,158,982, Nov. 2, 1915.)

Briquetting Process.—A process for making briquets from iron ore, flue dust, pyrites cinders, etc., for smelting is patented by Mr. DANDRIDGE H. BIBB of New York City (assigned to the Continental Process Corporation of Briarcliff Village, N. Y.). In the process the binder used is pyroligneous tar obtained from wood distillation. In briquetting flue dust it has been found that from 6 to 8 per cent by weight of pyroligneous tar will give a good briquet. The tar is first heated to the viscosity of a heavy mineral oil and then mixed with the granular material in any suitable apparatus. The mixture is then pressed into briquets and heated for ten to fifteen minutes to 250 to 300 deg. C. It is claimed that no disagreeable fumes will result. Another patent of the same inventor proposes to use as a binder the waste liquor obtained in the sulphite process of paper making. This liquor is evaporated to 30 or 32 deg. Baumé and mixed as above and the briquets pressed and heated for about twenty minutes to 300 deg. C. This treatment is claimed to give a water-proof, strong and compact briquet and to overcome all the previous difficulties experienced in using waste sulphite liquor as a binder. Another patent proposes to use as binder the waste sulphite liquor from the manufacture of chemical wood pulp. This binder is used the same as those mentioned above. Still another patent proposes to evaporate the waste sulphite liquor from paper making until a hard soluble pitch-like residue is obtained. This is

pulverized, a solution made of it and mixed with the material to be briquetted. The treatment from then on is the same as in the preceding patents. (In the order mentioned the patents are 1,158,363-4-5-6, Oct. 26, 1915.)

Gold and Silver

Slime Filter, and Method of Forming and Washing Solid Cakes.—In the ordinary process of filtering ore slime for the recovery of valuable solution, it is customary to use vacuum filter leaves on which a cake will be formed. The leaves are spaced apart and the cake formed on any leaf is not formed thick enough to come in contact with the cake on an adjacent leaf. These leaves may be inclosed in a drum into which the material to be filtered may be forced, and the process of filtration caused to proceed by pressure. In patents granted to DAVID J. KELLY of Salt Lake City, Utah, the inventor describes a method of forming "solid cakes," that is, cakes which are continuous between adjacent filter leaves. He also discloses his method for effectively washing such cakes. His filtering apparatus consists of leaves within a drum, with suitable connections through the container for the withdrawal of the filtrate. These connections are combined in a manifold pipe with necessary valves for controlling the flow of solution. In operation, the ore slime is forced into the drum and the separation of liquid and solid takes place under pressure, the liquid issuing from the drum and the solid forming a cake on the filter leaves. Filtration is continued until a solid cake is formed between filter leaves. In order to wash such a cake, valves are so arranged that water can be forced into alternate leaves, whereupon it passes out of these leaves through the cakes on either side and into the intermediate leaves from which it again issues from the drum. When the cakes have been sufficiently washed they are discharged by opening one end of the drum and running the leaves out on a track. The leaves may be flexibly mounted, and by moving them laterally the cake will be dislodged. (1,158,055, Oct. 26, 1915.)

Zinc-Dust Feeder.—Apparatus for emulsifying and feeding zinc-dust in measured quantities in accordance with the gold and silver content of cyanide solutions, is shown in vertical section of Fig. 4, being patented by HERBERT C. COLBURN of Victor, Colo. It consists of a supply bin 3 for zinc-dust, under which is mounted a screw conveyor 7. The latter is intermittently rotated by a friction ratchet 8 and oscillating member 9 which, by means of an adjustable pitman 10, is connected with gearing driven from a line shaft not shown. The pebble mill 20 is driven from the same line shaft. The dust discharged

FIG. 4—ZINC-DUST FEEDER

by the action of the screw falls into a bowl 16, from which it is borne to the pebble mill by a stream of barren solution issuing from pipe 17. The quantity of zinc-dust fed to the mill during any fixed period is determined by the capacity of the scoop 21, and the rate of velocity of mill rotation, so that there will be a continuous uniform discharge of emulsion from the hollow trunnion of the mill after the ma-

terial has been subjected to the grinding and emulsifying action of the pebbles, of which the mill is about one-third full. (1,149,426, Aug. 10, 1915.)

Copper

Melting and Refining Copper.—An improvement on the practice of melting and refining copper in a furnace having silicious walls and bottom is contained in the specifications of patent granted to LAWRENCE ADDICKS of Perth Amboy, and CLARENCE L. BROWER of Chrome, N. J. According to the improved practice the copper is treated in a furnace having walls of chrome brick and hearth of magnesite brick. A furnace thus constructed with basic lining is not subject to the erosion and consequent weakening of the structure as with acid lining. Furthermore, the contamination of the molten copper with slag is practically avoided. The practice is of value in the treatment of the three classes of materials ordinarily dealt with in copper refining, viz., foul material, blister copper and cathode copper. The basic furnace permits the treatment of foul material by itself, without the admixture of large quantities of relatively pure material as in acid-furnace treatment. In refining blister copper the basic treatment diminishes the production of slag. In melting pure cathodes, slag is practically suppressed instead of being formed to the extent of about 3 per cent as in acid practice. In any refining of copper the molten charge after skimming should be covered with a layer of carbonaceous material to avoid further oxidation, and precautions should be taken against the introduction of slag from fuel ash. (1,148,814, Aug. 3, 1915.)

Continuous Leaching Apparatus.—The interest being taken in the leaching of copper ore is reflected in apparatus patented by M. C. GODBE of Salt Lake City, Utah, for the continuous treatment of ore by the principle of counter-current flow of solution. The device consists of an annular rotating table, the deck of which is divided by radial partitions into segmental filter units. Beneath the table is a stationary annular launder divided into compartments corresponding in number with those of the deck, and provision is made for the filtrate to flow into this launder. Above the table deck are stationary solution boxes or launders occupying positions above the radial partitions which divide the deck into filter units. Means are provided for feeding the ore onto the table and for removing it after it has been leached. Injectors or air-lifts are also provided for transferring the filtrate from any compartment of the launder beneath the table to the next preceding solution box above the table, in relation to the direction of rotation. In operation the ore is delivered onto the revolving deck in a uniform layer, and as the table revolves it brings the ore on each unit successively under the boxes from which leaching solution is delivered over the charge. As the ore progresses from the point of feed to that of discharge it is acted upon by solutions of gradually increasing strength, and when it reaches the last step in the treatment it receives the strong or barren solution. Water is used for displacing the barren solution just before the ore is discharged from the table. Since the injectors transfer the solution in counter-current to the "flow" of ore, the liquid becomes enriched in metal content as it progresses toward the point of initial treatment, whence it is drawn off for recovery of metallic copper. (1,150,263, Aug. 17, 1915.)

Nitric Acid Treatment of Copper Ores.—In the issue of this journal for November, 1911, page 571, there was a description of the so-called Rankin process of ore treatment. Those who are interested in following the matter still further will find the claims for nitric acid

treatment disclosed in a patent granted to HARRY D. RANKIN of Crafton, Pa. The process is about to be operated by the Nevada-Douglas Consolidated Copper Co., at Ludwig, Nev. (1,150,787, Aug. 17, 1915.)

Electrolysis with Revolving Electrodes.—Electrolytic apparatus for the treatment of copper solutions at greater efficiency has been patented by WILLIAM E. GREENAWALT of Denver, Colo. The essential feature of the device lies in means for rotating the anodes in order to bring about a rapid change of solution in contact with the electrodes. A diaphragm separates the cell into anode and cathode compartments. The invention is applicable to the treatment or cyanide solutions of gold and silver as well as to those of copper salts. (1,144,538, June 29, 1915.)

Zinc

Device for Cleaning Retorts.—An invention which may be described as a "vacuum cleaner" for the retorts of a zinc furnace is described in a patent issued to NICHOLAS L. HEINZ of La Salle, Ill. The object of the invention is to reduce dust losses in cleaning retorts and conveying the dust to a place of deposit. A vacuum pipe is extended along the front of a furnace, with a plurality of fittings to which a flexible hose can be connected. The flexible hose terminates in a pipe which is inserted into the retorts, and through which the dust is drawn to a suitable container. (1,160,077, Nov. 9, 1915.)

Roasting Zinc Flotation Concentrates.—The difficulties encountered in roasting the fine concentrates produced in the flotation process have resulted in devising various means of roasting such material without entailing excessive dust losses. One of these is disclosed in a patent granted to LOUIS C. DREFAHL of Cleveland, Ohio, the patent being assigned to the Grasselli Chemical Co. of Cleveland. The essential features of the invention consist in mixing the fine concentrates with moisture to make a plastic mass, and possibly with a binder such as ferrous sulphate. This mixture is then conditioned in a pug-mill and then expressed through a perforated plate, issuing in a number of streams of pulp, each about the diameter of a lead pencil. These fall onto an endless moving belt and break up into short fragments, and are carried by the belt through a furnace chamber where they are dried by hot gases. The material thus treated is said to withstand handling by shoveling or otherwise without much further disintegration, and can be roasted without undue dust loss. (1,153,203, Sept. 14, 1915.)

Smelting Zinc Ores.—With the object of increasing the yield of spelter in the smelting of zinc ores, and simultaneously decreasing the production of blue powder, SAMUEL PEACOCK of Philadelphia, Pa., has patented a process of smelting zinc ores by substituting silicon carbide for carbonaceous fuel in the smelting mixture. The reaction of the mixture would be represented in the following equation:

With three equivalents of zinc being given off, the concentration of zinc vapor in the furnace gas would be three times as great as with the present method of smelting, and therefore a much larger proportion of the zinc in the ore would be recovered as molten metal without reducing the concentration of vapor to the point where blue powder would be produced. (1,154,802, Sept. 28, 1915.)

Recovery of Zinc from Zincky Slags.—Attempts have been made at various times to recover in an economical way the zinc contained in slags produced in Western smelters. One of these is outlined in a patent

granted to SEWALL TRUAX of Canon City, Colo. The process was used for a short time at Canon City on zinky slag from the dump of the United States Smelting Co. The principle of the method is to melt the slag in a reverberatory furnace, the hearth of which is composed of reducing material, such as a mixture of coke dust and clay. The coke reduces the zinc compounds to elemental zinc which is then volatilized. Later the zinc is converted into oxide in the atmosphere of the furnace, and this is collected in a bag house. The consumption of carbon is about 20 per cent of the zinc driven off; or, in the case of a slag containing 10 per cent zinc, the consumption of coke is about 2 per cent of the weight of slag treated. The inventor states that experiments indicate that the zinc above 0.5 per cent to 0.6 per cent of the weight of the slag is readily removed. Of course the hearth of the furnace has to be renewed from time to time. (1,155,628, Oct. 5, 1915.)

Hydrometallurgy of Zinc.—In the accompanying Fig. 5 we illustrate in diagrammatic form the steps in a process for the extraction of zinc from its ores and the electrodeposition of zinc thus extracted. The

FIG. 5—HYDROMETALLURGY OF ZINC

process is one patented by OTTO BEST of San Francisco, Cal. The features of the process lie in the purification of the zinc sulphate solution before electrolysis. The prepared ore is leached with sulphuric acid. Iron, alumina and silicic acid are removed by treatment with lime, followed by filtration. The next step is the removal of manganese by adding to the zinc sulphate solution an alkaline permanganate, such as calcium permanganate, in the presence of lime or calcium carbonate. This precipitates manganese as the dioxide which is filtered off. Copper is then removed by treatment of the solution with an excess of granulated zinc

and removed by filtration. The filtrate is now practically pure zinc sulphate solution, and as much of it as is needed is used to fill and keep filled the electrolytic vat. Zinc hydrate is now precipitated from solution by means of hydrated lime. The precipitate is filtered and the water therein displaced with strong electrolyte, after which the precipitate is held in suspension and fed to the acid neutralizing tanks as required. From the cell the acid electrolyte passes to a sump where suspended matter is removed, after which the electrolyte passes to the acid neutralizing tanks where the acid is neutralized with the zinc hydroxide precipitate. Neutralization and electrodeposition are effected cyclically by means of the freshly precipitated zinc compound, without, however, diluting the electrolyte, the strength and purity of which are constantly maintained. (1,154,602, Sept. 28, 1915.)

Extraction and Electrolysis of Zinc from Smelter Fume.—In a patent granted to OTTO BEST of San Francisco, Cal., the inventor describes his method of treating smelter fume for the recovery of contained zinc. The experiments were performed on a smelter fume containing from 30 per cent to 35 per cent zinc in the form of oxide and sulphate. The fume is first roasted at a temperature below that of sulphatic roasting. By this treatment the material is rendered filterable; the organic matter is destroyed; the material is freed from arsenic which can be recovered; iron is oxidized and rendered practically insoluble in weak acids, and small amounts of sulphides are oxidized to oxides and sulphates.

FIG. 6—ELECTROLYSIS OF ZINC SULPHATE

The roasted material is then leached with weak sulphuric acid, whereupon zinc is dissolved and a solution obtained which is much purer than one produced by leaching the unroasted fume. All impurities can be removed by zinc oxide and a little sodium sulphide, used either successively or in one process, according to the impurities present. From the highly purified zinc solution zinc hydroxide is now precipitated by means of a caustic alkali, and soluble impurities removed by washing and filtration. Electrolysis of the zinc compound can then be accomplished by a manner illustrated in Fig. 6 in which *C* represents a cell filled with zinc sulphate. This runs over into a storage tank *S* and contains zinc sulphate and some sulphuric acid. A pump *P* lifts the solution to two filters *A*₁ and *A*₂, having false bottoms and filled with the precipitated zinc hydroxide mixture. The solution is run through these filters at such a rate as to produce the desired acidity in the cell *C*. The practically neutral solution from these filters may pass through another filter *A*₃, which also contains zinc hydroxide precipitate, to get rid of any possible traces of free acid, and then delivered to the cell *C* in a pure neutral state, when a small amount of sulphuric acid, best suited for the electrolysis, is added. (1,154,601, Sept. 28, 1915.)

Synopsis of Recent Chemical and Metallurgical Literature

Zinc

Lungwitz Zinc-Smelting Process.—At a recent meeting of the New York section of the Mining and Metallurgical Society of America, Mr. WOOLSEY MCA. JOHNSON gave his experience with an unsuccessful attempt to operate the Lungwitz process of smelting zinc ores under such pressure that the zinc vapor was kept liquified. This process was patented by Dr. Emil Lungwitz about twenty years ago, and some spelter was produced experimentally by Dr. Lungwitz and Dr. Robert C. Schupphaus in Berlin. On the basis of the experimental work, Mr. John E. Dwight fathered a scheme to try the process on a larger scale for the treatment of a complex zinc ore, obtaining copper matte, lead bullion and spelter. The ore tested was from New Hampshire and contained 20 per cent zinc, 7 per cent lead and 1 per cent copper in a mica gangue. The pressure blast furnace was erected at Warren, N. H. The talent engaged comprised Fred C. Gordon, E. A. Uehling, D. V. Keedy, Carl F. Dietz and Mr. Johnson.

"The apparatus used was a round, pressure blast furnace, 3 ft. inside at the tuyeres, 5 ft. 6 $\frac{3}{4}$ in. at the bosh, with a height from tuyere line to charging floor of 25 ft. 3 in. The furnace was supported by four steel battered columns of latticed channel bars. The crucible was thus exposed to view. Five 3-in. water-cooled tuyeres were used, in each of which a bronze plug with three $\frac{7}{8}$ -in. holes diffused the blast into the smelting zone. The shaft was made of $\frac{7}{8}$ -in. plate, triple riveted. The charging was done by a massive double bell and hopper of cast steel. The pressure in the furnace was regulated by two "bleeders" on top, like safety valves. The crucible and bosh were lined with chrome brick, and the shaft with good fire brick. It was possible to spray with cooling water any section of the furnace, which was blown by a two-stage Ingersoll-Sargeant 7-drill compressor giving 1000 ft. of free air per minute. In general, it resembled a conventional iron blast furnace, modified to meet the imposed conditions of operating at 60 lb. pressure. The engineering effect was as good as could be desired, when the unusual and difficult nature of the feat was considered.

"As a result of discussion it was seen that the pressure and temperature limits of the smelting zone would be at least narrow. It was accordingly determined to make a pressure-temperature curve of the system "liquid-vapor zinc" and fluidity tests on the running points of various slags.

"For the first-named purpose, after several trials a 'bomb' was made of a piece of 5-in. shafting 30 in. long, drilled with a 3.5-in. hole. In one end, the lower, an outside hole was drilled to receive a pyrometer couple in close proximity to 500 grams of spelter. The bomb was placed inclined in a small kerosene-fired reverberatory so that the upper end projected through a luted hole in the furnace. There was a pipe connection from this to a small receiver, which had a pressure gauge and a relief-valve operated by hand. In this way the line pressure of 120 lb. could be controlled to any desired pressure from zero to 120 lb. In the bomb, 3 in. from the molten zinc was a 0.01-in. hole and 3 in. from this a second 0.01-in. hole. The bomb was filled with coke (88 per cent fixed carbon) sized between 4-mesh and 10-mesh. Thus, when the bomb was under heat and pressure two small flames of carbon monoxide burned from these two tiny apertures. When the pressure was slowly reduced, the carbon monoxide flames suddenly changed to brilliant zinc flames when the boiling pressure of zinc at that temperature was reached.

"After some failures, we found it necessary, after each determination of the boiling point of the zinc, to increase the pressure so as to clean the coke from all zinc either as liquid or vapor. In this manner all false flames caused by "fuming" were eliminated. It was also found necessary to shut off the oil flame while taking the readings, as the indicating flames were otherwise not easily visible. When the details of operation were understood, accurate and comfortable results were attained. The curve above the boiling point of zinc at atmospheric pressure, i.e. 920 deg. C., is nearly a straight line, and for each pound increase in pressure the boiling point is raised 6.1 deg. C.; at 25 lb. it is 1080 deg. C.; at 75 lb., 1350 deg. C.

"For determining the fluidity of slags we used the Johnson slag-tester, described in *Trans. A. I. M. E.*, Vol. XLIV, page 139. This gives accurately the temperature at which the slag in question drips through a small hole, a point analogous to that at which the slag in the smelting zone drips over the coke. We made and tested about 70 slags, and finally determined on a sesquisilicate containing 8 per cent CaF_2 , 15 per cent FeO , 5 per cent Na_2O , remainder lime and silica. This slag is fluid at a few degrees above 1000 deg. C., whereas lead blast furnace slag is fluid at about 1100 deg. C. It was impossible for use to use a high percentage of ferrous oxide, for fear of formation of "iron sows," under the more intense reduction needed in the Lungwitz process.

"With knowledge of these factors, we could operate the furnace with some degree of certainty. There was raised, however, the question of "the law of partial pressures." For liquifying any vapor, the full pressure of the vapor must exist next to the surface of the liquid. Now, in the furnace operations at Warren, for each cubic foot of zinc vapor there were some 9 cu. ft. of indifferent gases, carbon monoxide and nitrogen, sweeping through the smelting zone. Accordingly, should any zinc be liquified it would be evaporated by this sweep unless the pressure were ten ($9 + 1$) times as large as had been considered and calculated. The condition was analogous to a steam condenser with too much air in the system. This point was brought out in discussion, but it was decided to start at any rate. It was found later that it militated strongly against the success of the Lungwitz process.

"The furnace was started, after three weeks' overhauling had made it tight to 80 lb. air pressure, by inserting a torch through the tuyeres and lighting cord wood on which was a charge of coke. Above that was a burden of coke and slag-making materials. Tests of the charging, pricking the tuyeres, and tapping slag were made. The pricking of the tuyeres made an infernal racket, but could be done successfully. Finally the slag level came up to the height of the tuyeres and a test of the slag-tapping arrangement was made. This was designed with a cast-steel hood in the form of a large ell over the slag notch, to which was bolted a cast-iron cylinder leading to a brick run-way for the slag. In the cast-steel were two holes, through the lower one of which a modified Scott "mud botting-gun" could be inserted. Through the upper hole, the tapping bar could be inserted. While the entire force retired to a considerable distance on the side hill, the writer and Mr. Allen, now superintendent of the Columbia works of the National Carbon Company, with internally repressed trepidation but with all possible show of sangfroid, attacked the position of the enemy. The bar was driven in with ease. On pulling it out, the slag was voided instantaneously in a large aerated mass, and ran down the run-way like a thing possessed; the mud-gun was next pushed by the pneumatic cylinder

against the slag-hole and the bott sent home. Contrary to my expectation, the tapping of slag and botting the furnace under 60 lb. pressure was successful in its first trial. Later, we repeated it at the working pressure of the furnace, and so long as the crucible of the furnace was hot and its contents liquid there was little trouble. The charging of the furnace gave but little trouble as the heavy bell and hopper were actuated by powerful air cylinders, and pieces of charge on the bearing surfaces could be shattered.

"The furnace ran along for three weeks but finally froze. I think that steam from the wet charge condensed in the ganister filling between the shell and the lining and finally made its way to the crucible. At all events, a lot of water got into the crucible, while there was no leak from the cooling systems. The furnace made no spelter at all, but the lead produced carried a few tenths of zinc. As the reduction was intense, the slag analyzed only a trace of lead. Some zinc, as was natural, was carried up the shaft and condensed. In a longer campaign, I believe that bad scaffolding would have occurred at intervals. The work at Warren was abandoned after this test. Mr. Gordon later built a furnace near Philadelphia having a shaft 60 ft. high and 4 ft. in diameter, with a condenser near the bosh. He finally made a few thousand pounds of spelter. With his death, the work was given up.

"We can thus chronicle the last and most serious attempt to make spelter in the blast furnace. The work was done with elaborateness, without regard to expense, and with all possible engineering care. It can be concluded that inherent metallurgical difficulties prevented the success of this scheme and will prevent that of any other similar scheme. In short, while a brilliant attempt had attained some success in working out apparently insuperable practical details to a certain degree, the law of partial pressures attacked the very heart of the process and made it faulty in theory."

Gold and Silver

Metallurgy of the Sons of Gwalia Ore.—In our issue for Dec. 1, 1915, we gave a synopsis of certain features of the plant of the Sons of Gwalia, Australia. This is now supplemented by some metallurgical details from an article by THOMAS B. STEVENS in the September *Journal* of the Chamber of Mines of Western Australia.

The ore is a sulphide of iron in a gangue of highly sheared greenstone schist containing quartz and calcite. Following is a typical analysis:

	Per Cent
Silica	68.40
Alumina	9.71
Ferric oxide	1.85
Calcium oxide	3.61
Calcium carbonate	11.94
Magnesium oxide	2.15
Pyrite	3.15
	99.91

The value of the gold content is slightly over 30s. (\$7.50) per ton; the gold is alloyed with one-twelfth its weight of silver. Free gold occurs in the quartz, but the pyrite is the richest part of the ore. The following grading analyses on a sample crushed to pass 30-mesh show the distribution of the value in the original ore and after it has been amalgamated.

Grade	Per Cent	Assay Value in Shillings Before Amalgamation	Assay Value in Shillings After Amalgamation	Extraction on Grade, Per Cent
+ 60	17.9	39.8	38.9	2.3
+ 150	20.2	46.0	30.9	30.5
- 150	14.4	112.0	26.0	76.8
Colloidal slime	47.5	12.0	8.0	33.3
Bulk (calculated)	100.0	38.2	29.3	46.8

Extraction by amalgamation is seen to be highest on the minus 150-mesh grade, even though this contains the greatest percentage of mineral; but equally

good extraction can be had on the plus 150-mesh grade if it is ground fine enough. For successful cyanide treatment, the economical limit of grinding is minus 150-mesh.

A feature of the rock-breaking plant is the use of a gyratory to crush in one operation a large tonnage suitable for stamp feed. The gyratory is well suited to the crushing of this ore, the greater part of which comes in flat slabs which would pass a jaw breaker without being crushed.

Stamps weigh 1225 lb. when new, having been increased in weight from 1000 lb. The old camshafts, 5½ in. in diameter, are found too light for the additional weight and show a short life. Cast-iron dies are used, as it has been found that a more constant tonnage can be crushed than with steel dies, on account of a more even wearing surface being maintained under the shoes. When crushing through screen of 0.097 sq. in. aperture, with a 4.75:1 ratio of water to ore, a duty of 10 tons per stamp per day can be maintained.

Grinding pans and tube mills are used for fine grinding. The former were part of the original equipment and are still used for amalgamating a part of the gold. Recovery by this method amounts to 20 per cent of the total, and the removal of so much gold at this point relieves the cyanide department of possible losses from high-grade solutions and soluble gold loss at the filters.

The following table compares the work of the different grinding machines:

	Total Cost Running One Unit One Day	Tons —150 Grade Produced Each Day per Machine	Percentage of Total Tonnage of —150 Grade Produced	Cost of Producing One Ton of —150 Grade, in Pence	Tons —150 Grade Produced per Hip. Day
Five stamps	2.65	18.0	38.0	35.4	1.20
Pan	1.36	7.4	15.0	44.0	0.59
Tube-mill	5.17	54.0	33.0	23.0	1.20

Some interesting figures have been compiled to show what proportion of the gold is dissolved at various points in the process. In each case estimates were made by determining the difference between the assay value of solutions entering and leaving the machines and then calculating to tons of dry slime.

	Shillings per Ton	Per Cent of Total Gold Dissolved
In battery boxes, less than	0.5	1.5
In pans	6.5	19.4
In tube-mills	2.7	8.0
In launders, classifiers and thickeners (estimated by difference)	5.0	14.9
In agitators	9.6	28.7
Total dissolved	24.3	72.5
Amalgamated in pans	6.7	20.0
Left in residue	2.5	7.5
Value of original	33.5	100.0

A high filter duty is obtained due to the porous nature of the slime. Using a vacuum of 27 in. and a pulp of 40 per cent solids, a cake 3 in. thick and containing 28 per cent moisture and 20.5 lb. dry slime per square foot can be obtained in 20 min. Each square foot of filter cloth filters nearly 20 tons of slime before it is discarded.

Loss of soluble gold in discarded slime is 3d. (\$0.06) per ton, and cyanide loss is under 0.1 lb. KCN.

In order to get good precipitation it is necessary to maintain the zinc-lead couple in the boxes. This is done by allowing a drip of lead acetate to run continuously, delivering about 0.3 oz. per ton of solution. This has been more efficient than coating the zinc with lead or introducing lead salts at the tube-mill or agitator.

The cost of treatment for the past six months, on an average tonnage of 13,534 tons has been:

Rock breaking and transport.....	\$0.0888
Stamp milling.....	.2678
Pan-grinding and amalgamation.....	.1456
Tube-milling.....	.1902
Agitation and filtration (including all water used for treatment purposes).....	.5490
Precipitation and smelting.....	.1504
Cost per ton.....	\$1.3918

Cyanide Consumption on the Rand.—In an extensive article by H. A. WHITE in the September, 1915, issue of the *Journal of the Chem. Met. & Min. Soc. of South Africa*, the author gives the results of his investigation into the causes of cyanide loss in Rand mills. The average consumption of cyanide on the Rand for 1914 was 0.4 lb. per ton of ore treated, and the annual requirement was about 5000 tons.

An estimation, as NaCN, of the amount of total cyanide, ferrocyanide and sulphocyanide in sand residue as discharged at the Simmer Deep showed a loss of 0.0344 lb. NaCN per ton of pulp in sand treated. A similar estimation on settled slime after treatment and before discharging showed a loss of 0.1219 lb. NaCN per ton of pulp in slime treated. Similar experiments with sand and slime at the Rose Deep showed NaCN losses per ton amounting to 0.0583 lb. and 0.0653 lb. respectively.

To determine the loss due to the escape of HCN from exposed solutions, experiments were conducted with sump solutions in glass jars of 300 c.c. capacity and a surface exposure of 84 sq. ft. per ton of solution, compared with 5 sq. ft. in a sump 6 ft. deep. The results showed that loose or incomplete covering is useless in preventing loss of cyanide; that with weak solutions little loss as free cyanide occurred while protective alkali was present; that with strongest solutions the loss, both as free and total cyanide, became serious when protective alkali fell below 0.01 per cent NaOH, and, finally, that zinc in solution greatly decreased the loss of HCN due to hydrolysis.

A further experiment was made with strong and weak stock solutions and new solutions without protective alkali, by placing duplicate quantities of each in open vessels and stoppered bottles, and titrating the free cyanide in each sample at intervals from six to ninety-five hours. The exposed solutions suffered notable losses of cyanide while the stoppered solutions remained at almost original strength.

Exposure tests with working solutions under varying conditions of temperature, time, alkalinity and cyanide strength, showed that the loss is much greater in pure synthetic solutions, even with added alkali, than with ordinary stock solutions; that higher temperature increased the loss; that high protective alkalinity reduced the loss by preventing hydrolysis.

Prevention of Hydrolysis in Cyanide Solutions.—This subject is exhaustively treated by HUGH M. LESLIE in the *Journal of the Chem. Met. & Min. Soc. of South Africa* for September, 1915. The author regards hydrolysis as responsible for great losses of cyanide in the treatment of gold ores, and gives the results of his investigations on the subject. He contends that the evolution of hydrocyanic acid due to hydrolysis is accountable for the large excess of cyanide which has to be used over and above that required for efficient extraction. As a remedy he proposes a "closed" system of cyanidation, in which the vats and tanks are covered. His ideas on this subject have been patented, the United States patent being reviewed in our issue for Dec. 15, 1915, page 972.

In a simple cyanide solution kept at temperatures

varying between 42 deg. and 49 deg. Fahr., the following losses were noted due to hydrolysis:

Interval, Hours	KCN Test, Per Cent	KCN Loss, Per Cent
4	0.368	7.56
24	0.232	37.00
22½	0.116	50.00
23½	0.028	75.80

With higher temperatures the loss is markedly increased, and in agitation with model Brown agitators there is a steady loss as agitation proceeds.

Exposure tests with simple cyanide solutions of different strengths show that the weaker the solution the greater the percentage decomposition. They also show that the alkali formed as a product of hydrolysis has little or no protective action on the remaining cyanide, and that hydrolysis proceeds until all the cyanide is consumed.

In contrast to these experiments, the author conducted tests in closed vessels, showing that the loss of cyanide is very small as compared with that in open vessels. He concludes that a very great loss must occur from hydrolysis in actual practice where the vessels are open, and that great protection can be afforded by a "closed" system.

In order to confirm his theories in actual practice he conducted tests at operating plants. At one mill he made tests on the slime department only, showing that there was a loss of cyanide due to evaporation amounting to 0.0013 per cent KCN per twenty-four hours, aggregating 32,572 lb. of cyanide (100 per cent strength) per annum. This figure did not include the losses in other departments, but serves to show the enormous loss which may be attributed to hydrolysis.

Parallel leaching tests were then made on a small scale with open and closed systems, in order to get comparative data on cyanide losses. The following average figures for cyanide consumption were obtained:

	KCN, Per Cent	Per Ton, Lb.
Open system.....	100	0.9375
Closed system.....	100	0.6283
Open system.....	130	0.4900
Closed system.....	130	0.3290

This shows a difference per ton of 0.2092 lb. 100 per cent KCN, or 0.1610 lb. 130 per cent KCN, or 33 per cent in each case.

The actual consumption in the tests was greater than is obtained in practice at the mill where the tests were made, figures for the latter being about 0.390 lb. 100 per cent KCN, or 0.300 lb. 130 per cent KCN. If these figures are used as representing the actual conditions, and the "closed" system consumption reduced by the difference between these actual figures and the test figures for open system, the comparative figures will be:

	KCN, Per Cent	Per Ton, Lb.
Open system.....	100	0.3900
Closed system.....	100	0.1806
Open system.....	130	0.3000
Closed system.....	130	0.1390

These figures show a saving due to protection afforded by a closed system amounting to 54 per cent in each case, or, based on a consumption of 0.3 lb. per ton with cyanide at 32 cents per pound, it would amount to a saving of about 5.2 cents per pound.

Similar tests on slime in agitators by the closed and open systems showed a saving of cyanide by the closed system. Other tests are given, all of which lead the author to conclude that there is possibility of making a marked saving of cyanide by using a closed system of treatment.

Bromine.—It is announced that the bromine wells near Pomeroy, Ohio, and Mason City, W. Va., have again been put in operation after an idle period of a number of years. The present production is expected to be 5 tons to 6 tons monthly.

A New Electrolytic Cell for Making Pure Oxygen and Hydrogen

The demand for oxygen and hydrogen for various industrial uses has grown very rapidly in the last five years. Certain lines of manufacture have been built up based on the oxygen process of welding, such as welded tanks, steel barrels, automobile parts, tubes, etc., while for repairing broken machinery, for reclaiming castings, for metal cutting of every nature, oxygen and hydrogen or oxygen and acetylene are used in steel mills, railroad shops, foundries and down to the smallest machine shop. Hydrogen likewise is in active demand; it is used more and more for cutting purposes and for light welding; it is also used for lead burning, platinum smelting, in the manufacture of filaments for electric lamps; and to a very great extent in the new industry of hardening oils by the hydrogenation process. This rapid development in the uses of two gases was facilitated by the introduction into this country of oxygen and hydrogen-generating apparatus several years ago. Large users of one or both of these gases were thus enabled to obtain their supply direct from their own generating plant at low cost, in a manner suitable to their individual requirements.

The International Oxygen Company of New York City, makers of the I. O. C. unit type generator, is bringing out a new style of oxygen and hydrogen generator under the name of the I. O. C. bipolar generator.

This type of generator resembles outwardly a filter press such as used in many chemical industries. Rene Moritz, of Wasquehal, France, patented this type of apparatus in the U. S. and elsewhere in 1913, and I. H. Levin, of the International Oxygen Company, who studied under Moritz and Flamand, perfected this machine greatly, and incorporated in it many novel and ingenious features.

Briefly described, the I. O. C. bipolar generator consists of a series of metallic plates (bipolar electrodes) clamped up together in a heavy frame, electrically insulated from one another, and separated by diaphragms of porous fabric. Each pair of these electrodes forms a closed cell divided by the diaphragm. These cells are filled with the electrolyte (caustic potash or soda solution).

An electric current admitted at one end plate passes on through the plates and the solution to the other end plate. In its passage it decomposes the water in the solution into the two gases—oxygen and hydrogen—which are released on opposite sides of each plate and emerge upward into the gas off-takes. The mingling of the oxygen and hydrogen in each cell or compartment is prevented by the diaphragm which, while permitting the passage of the fluid resists the passage of the gases.

As the gases are released and withdrawn water is automatically added from a supply tank. The operation is continuous so long as current and electrolyte are supplied.

In the smaller machines, the electrodes are carried on two steel rods supported on two heavy end pieces or pedestals of cast iron. In the larger generator the side rods are replaced by steel bars. The construction is one of extreme rigidity, absolutely proof against any distortion and consequent disarrangement of electrodes, with resultant leakage. It will be noted that there are only the two end supports—no middle support as in some types—simplifying the problem of erection and alignment.

The electrodes are clamped together by a heavy screw working in the rear support. A feature of special

note in the I. O. C. generator is that a ball thrust bearing is interposed between the end of the clamping screw and the rear end plate—a refinement which contributes to the non-leaking qualities of the machine by doing away with the tendency of the electrodes to "ride up" from the side bars under screw pressure.

The electrodes are of a special patented design, the anode side being heavily nickeled, while the cathode side is of commercially pure iron. This use of two metals has an important bearing upon the efficiency of the generator, referred to more fully later. The surfaces of the electrodes carry vertical corrugations which are interrupted by a large number of recessions to facilitate the flow of electrolyte into the cell and the release of the gases from it.

At top and bottom of each electrode are two openings communicating by a cored channel with opposite sides of the plate. Those at the bottom are for the water intake and those at the top are for the gas off-take. It will be seen that each half of each cell (separated by the diaphragm) has its own independent water intake and gas outlet, so that there can be no possibility of the two gases mingling through these channels. Any gas leakage which may occur between the electrodes escapes to the open air and not into the adjacent cell or into the gas off-takes.

The diaphragms are of especially prepared asbestos fabric, of a thickness and texture carefully worked out by long experiment to give the best results. All around the edge of this fabric is molded a packing rim of pure rubber which rests in a recessed groove on the face of the electrode.

Obviously, in a generator of this kind, an essential of power economy is that all the current supplied the machine shall pass through the electrolyte and none

PLATE WITH DIAPHRAGM

of it be by-passed through the metal of the machine or through the water inlets and gas outlets.

In the I. O. C. bipolar generator the electrodes are insulated from the side bars of the frames by porcelain insulators resting on a wooden bar in the large machine and on fibre in the small machine. They are insulated from one another:—first, by the pure rubber packing rim surrounding the diaphragm; second, by nipples of pure rubber inserted in the water intake and gas off-take shoulders of the electrodes. These nipples, with everything clamped hoe, meeting one another and not only insulating the electrode shoulders but also providing an insulating tube in the interior of the water intakes and gas off-takes.

The gases rising from the electrodes and entering the gas off-takes, carry with them a small percentage of the electrolyte which, if allowed to enter the external piping system, would "ground" the apparatus and permit the escape of current.

To guard against this contingency, there is provided in the gas off-take system insulating pipe sections—each consisting of two sections of heavy glass tube clamped between iron flanges and so devised as to intercept and drain off through an insulating connection the moisture entrained in the gases. The gases go through these insulators substantially dry and free from electrolyte.

The voltage supplied to any electrolytic gas generator is utilized in two ways:—partly in decomposing the electrolyte; and partly in overcoming the internal resistance of the generator.

A number of features of the I. O. C. generator contribute toward high electrical efficiency. First of these is the use of the nickel anode and iron cathode (a patented combination) which has been found to materially facilitate the electrolysis or decomposition, by lowering the "over-voltage." Incidentally, these bi-metallic electrodes prevent the formation of rust and oxides which would materially shorten the life of the apparatus.

A second feature in efficiency is the fact that the design of this generator is such as to retain within the apparatus most of the heat produced as a result of the ohmic resistance. This keeps the electrolyte and the

electrodes at a comparatively high temperature which adds to the efficiency of the electrolytic process. Furthermore, the electrolyte used—a solution of caustic potash—has been found by experiment to utilize the current to best advantage.

The generator is filled, on starting the apparatus, with the solution constituting the electrolyte. Obviously, as decomposition proceeds and gases are withdrawn, water must be supplied to the solution to maintain the right level and right density. On the front of the generator are two tanks or domes with glass water level indicators, which carry the solution. Pipes descend from these tanks to a water-feed manifold which branches into two pipes connecting independently to the two water intakes to the cells and also into two risers leading to the two independent gas domes above. Into these domes the oxygen and hydrogen are separately discharged as generated, the gas off-takes opening through an inverted U below the fluid level.

Next to these domes is a feed-water tank discharging distilled water through a float-controlled valve, as needed, to the solution tank on the front of the generator.

Arrangements are such that the proper fluid level is automatically maintained throughout the system. The two independent water intakes to either side of each electrode absolutely prevent any mingling of oxygen and hydrogen through the water supply.

This water-feed device creates an absolute balance of pressures throughout the generator, the vital importance of which will now be noted. Furthermore, it makes the water feed absolutely proportioned to, and under the control of, the rate of gas generation.

A primary essential in a generator of this type is to minimize circulation through the diaphragms—the function of these diaphragms being only to segregate the two gases as released at the same time permitting the passage of the electrolyte through their pores.

The two independent water supplies—one to either side of each diaphragm, but both under exactly the same pressure due to the hydrostatic head in the solution tank—obviously put the diaphragms under balanced fluid pressure, and eliminate circulation through them due to unequal pressures on their two sides.

This has two vital results. First, it removes any tendency to cause a mingling of gases through the diaphragm. Second, it relieves the diaphragm material from all mechanical stress and obviates any destructive erosive action which might be caused by solid particles in the electrolyte being forced through the fabric. This absolute balance and control of water pressure, then affects both the purity of the gases and the life of the apparatus.

The two gas off-takes discharge into the two independent gas domes already referred to, the gas emerging below the fluid surface through an inverted "U." It is apparent, then, that the pressure on both gases, clear back to the individual cells, is the same—being that determined by the hydrostatic head in the domes through the two independent risers from the water-feed manifold.

This balanced pressure in both gas off-takes prevents any mixture of the gases and contributes to the balancing of pressures on the diaphragms. It will be noted that gas and water pressures are predetermined and constant.

The gases, escaping from the gas off-takes rise through the fluid in the gas domes and pass out through discharge pipes at the top of the domes—thence downward to purgers in either side. These purgers are closed boxes of cast iron filled with water to a certain level. The gases except below the surface of this water, pass

I. O. C. BIPOLAR OXYGEN AND HYDROGEN GENERATOR.
TYPE G

upward through it, and emerge thence through the supply lines to the gas holders.

The function of these purgers is three-fold:—first, to catch any entrained fluid in the gas; second, to cool the gas; third, to act as a water-check-valve protecting the pressure system of the generator from any undue pressure of the gasholders.

A signal whistle is provided which gives notice when the level of the solution in the generator falls below the described limit. Glass sight-feed indicators on the solution tank and gas domes show the fluid levels and reveal the generation of the gases. Gauge glasses connecting with the electrodes at intervals along the generator show the fluid levels in the body of the apparatus.

To permit the emptying of solution from the generator when required, drain valves are provided. These are of the lever-operated gate type, designed to obviate any leakage or wear due to the presence of solid matter in the fluid.

To summarize, the notable features of the machine are:

First, the water feed to the generator is automatic and controlled entirely by the quantity of gas that the generator makes.

Second, the water feeds to the oxygen and hydrogen compartments are entirely independent, preventing mechanical transportation of the gases.

It is not to be inferred from this that the company recommends that these machines be started and then left absolutely to themselves. No mechanism is perfect—and the best apparatus made deserves a fair measure of consideration and attention. But it is claimed that the I. O. C. bipolar generator certainly calls for the minimum of attendance—at the most, only a small part of one man's time. And this feature contributes largely to the low cost of gas production to be realized by this apparatus.

New Uses of Monel Metal

Monel metal, the well-known alloy of approximately 68 per cent nickel, $1\frac{1}{2}$ per cent iron and $30\frac{1}{2}$ per cent copper, is finding its greatest uses and possibilities as an engineering alloy owing to its great strength and non-corrosive properties. The metal is commercially available in ingots, sheets, rods, castings, wire and a variety of other forms. The U. S. Government, through the Navy Department, has made tests which led them to specify it for outboard connections of battleships which would be rapidly corroded by sea water. Valves, valve seats and liners of cast Monel metal for pumps have been found very useful. Liners show no scoring, and after a short period of use assume a glass-like finish which reduces the packing to a minimum. The U. S. Navy requires all pumping equipment of ships be furnished with Monel metal.

IMMENSE VALVE FOR SUPER-HEATED STEAM

In connection with very high steam pressures, where superheated steam is used, the alternate heating and cooling of bronze and steel valve seats cause them to become granular and crumble away. Monel metal has been given a severe test and found entirely satisfactory. A large valve of Monel metal weighing 3500 lb. is shown in the accompanying illustration. This valve was made by the Nelson Valve Company of Philadelphia for the Philadelphia Electric Company's new station, where the largest steam turbines in the world (30,000 and 35,000 kw.) are installed. This valve is made to withstand 250 lb. pressure and 800 deg. Fahr.

Monel metal castings have found a varied use where chemicals or other corroding agents must be handled, such as in washing apparatus; acid conductors, in refrigerating plants where the ammonia causes rapid corrosion; for pickling apparatus in connection with the rolling of steel sheets and tin plate. Several of the largest mills for rolling steel sheets have recently changed their entire equipment from iron to Monel metal. Among such plants may be mentioned the Illinois Steel Company, the West Penn Steel Company, and, most notably, the Vandergrift Plant of the American Sheet & Tin Plate Company, which is the largest rolling mill in the world.

Electric Power Development in the Pittsburgh-Wheeling District

The American Gas & Electric Company, 30 Church Street, New York City, owner of several operating plants throughout the Eastern and Central States, has purchased about 600 acres of land at Beech Bottom, or Windsor, W. Va., on the Ohio River, between Wellsburg and Wheeling, and is proceeding with the erection of a large electric power plant on a portion of this land.

This will be a wholesale plant; that is, it will supply power to the company's present plants at Wheeling, Canton, Newark, etc., and will also be in position to furnish power to other electric companies, street railways, manufacturers, etc.

The original installation will consist of two 30,000-kw. turbines, or a total of 60,000 kw. The plans, however, contemplate an ultimate capacity of 200,000 kw.

The plant is designed by Sargent & Lundy, Chicago. Contracts have been let to the Foundation Company, New York, for the installation of intake tunnels, building foundations and turbine foundations. The General Electric Company will furnish the turbines and Babcock & Wilcox Company the boilers. It is expected the plant will be ready for operation some time in 1916.

Contract has been made with a neighboring mine to supply the fuel requirements of the entire plant for the next forty-five years.

A double-circuit heavy steel line will be at once constructed to Canton and operated at 140,000 volts. Connection will also be made with the company's present system at Wheeling and Newark.

This new installation is expected to attract to the Pittsburgh district a number of industries to whom cheap electric power is an essential. It is planned to supply local business adjacent to the plant at 11,000 volts directly from their busbars, and it is the intention to invite consumers with high-load factors, such as chemical and steel furnaces, to locate near the power plant. With this in mind, the American Gas & Electric Company, in making their purchases of land, secured sufficient acreage to accommodate a number of such industries adjacent to the generators.

The statement is made by the company that the low price of coal in this district, the abundance of condensing water, low cost of disposal of ash, which will be

used to fill up lowlands, and the absence of high tax rates will make it possible to produce power at a cost which will enable them to sell it to consumers cheaper than it would be possible for the latter to manufacture it themselves.

Device for Reversing Open-Hearth Steel Furnaces

The Schumann device for reversing open-hearth steel furnaces, which is described in the following note, has been in continuous operation for the past seven months in a large steel plant in Maryland and has given full satisfaction. Its operation is shown in Fig. 1.

1 is the open-hearth furnace which is to be reversed every twenty minutes, 2 is a clock with hour hand forming a contact which operates the solenoid 3. The plunger 4 is thereby raised, opens the four-way valve 5, which controls the passage of air, water, etc., through the pipe 6. The air or water enters the cylinder 7 and pushes the piston 8, which slacks the cable 9, dropping the water-cooled damper 10 and shutting off the stack draft. When the water-cooled damper drops, the clamp 11 hits the nut 12, which raises the damper 14 by the pulling cable 13. This lets in the air, which goes to the checkers and then to the furnace. The damper lid can be adjusted, letting more or less air come in by the screw device 15.

When the piston 8 is over it will permit slack on the cable 17. When the cable 18 is slack the burner 19 will slide into the furnace and automatically starts operating. There is sufficient slack in the cable 18 so that the counterweight 20 will drop, pulling the cable 21, which pulls the burner 19 into the furnace. Cylinders 22 will open, letting on the steam and oil the moment the burner starts sliding into the furnace. Cooler 23 will

protect the burner 19 when in and out of operation.

In case it is desired to reverse the furnace in less than twenty minutes, the button *a*, operating solenoid 3, is pressed. When the piston 8 is pulled over it has also pulled on the cable 24, which raises the water-cooled damper door 25, letting the stack draft pull on this end of the furnace. When the door 25 is raised up, the clamp 26 attached to it raises the nut 27, slackening the cable 28, which lets the damper lid 29 close, shutting off the air from the checkers. Piston 8, when pushed over, pulls on cable 30, which pulls the burner out of the furnace. Cable 30 raises the counterweight 31 and the sheave 32, which in turn slacks the cable 33 so that the burner 34 will come out of the furnace. The counterweight will then take up slack in cable 30, which is left over, so the burner 34 will remain out. When the burner 34 slides out it lays in cooler 35, which prevents it from being burnt up by flame from the opposite burner. When the burner starts sliding out of the furnace it ceases operating instantly, cylinder 36 shutting off the oil, steam or air.

When the furnace is ready to reverse twenty minutes later, the clock hand will touch the next contact point operating solenoid 3*a*, which opens the four-way valve and then operates everything in the opposite manner. If it is desired to reverse in less than twenty minutes, the button *b* is pressed. In case it is not desired to use the cable device to pull burners in and out of operation, a small slide valve can be used which lets the air, steam, water, etc., go to the small cylinders operating the burners in and out. When wanting to cool the furnace quickly for any particular reason, water-cooled dampers 10 and 25 are hung up, which will let the stack pull on the furnace from both ends.

This device is made by the Codd Tank & Specialty Company, Baltimore, Md.

SCHUMANN REVERSING DEVICE

Flotation Test Tank for Mill or Laboratory

In cyanidation it is considered safe and good practice to run pilot tests on the pulp parallel with the commercial treatment. In oil-flotation treatment the same rule should hold good. For this reason a small tank suitable for pilot-testing at operating commercial plants or in the laboratory has been designed by the Parral Tank System of Agitation, I. W. Hellman Building, Los Angeles, Cal. Although the apparatus and the principles of operation are patented, the free use of this tank is offered to any one for testing purposes.

Fig. 1 shows the dimensions of this tank and the operating apparatus embodied in its construction from which the tank may be made at any works. If the air pressure available for use is found too high, a short rubber or canvas sleeve may be slipped over the discharge orifice of the transfer pipes and directed downward in the tank charge.

The various parts of the tank and apparatus are lettered in the drawing as follows:

- AA is the line through plan view of top of tank on which the vertical elevation is drawn.
- a are transfer pipes through which the pulp is continuously drawn from the bottom and spouted 2 in. underneath top of tank charge.
- b is the arm from which the skimming paddles *c* are suspended.
- c are skimming paddles (pieces of rubber belt), 8 in. x 8 in., attached to, but swinging loosely on, the arm *b* by strap hinges *d*.
- d are the strap hinges referred to under *c*.
- e is an iron hoop around the top of the tank, but $\frac{1}{4}$ in. above it, to furnish a rest on which the arm *b* slides.
- f is a pin fastened through the center of the arm *b*, which drops into a hole bored in the wooden filler *F*, the center of rotation for the arm.
- F is the wooden filler in center of the tank to occupy space and reduce the holding capacity of pulp, thereby obviating the necessity of fine grinding a larger sample of dry pulp.
- g is a handle on the arm *b* by which the arm is revolved by hand to skim off the mineral-laden froth.
- h is a baffle-board to intercept the flow of froth around in the mixing circle and deflect it outside into the box *o*.
- i are eye-bolts by which transfer pipes *a* are fastened in place.
- j is the reducer fitting at the intake end of the transfer pipes *a*.
- k is a compressed-air pipe nozzle through which the compressed air is introduced into the transfer pipes.
- l is the iron flange into which the compressed-air nozzle *k* is screwed.
- m are lag screws which fasten the filler *F* to the bottom of the tank so as to give it a central position in the tank.
- n is the iron handle for the wooden plug in the outlet pipe *p*, by which this plug is placed or removed.
- o is the receiving box for mineral-laden froth.
- p is the pipe through which mineral-laden froth is discharged.
- q is an outlet in the bottom of the tank through which the treated pulp is discharged.
- r is the pulp level of the charge to be treated.
- s is the layer of mineral-laden froth formed on top of the pulp.
- t is the pulp-filled "mixing circle," within which the pulp is kept in agitation and in which the froth is created and rises mineral-laden to the surface.
- u is a small iron strap clamped across the bottom open-

ing of the reducer *j*, through the center of which the air nozzle *k* enters and is held in place.

In the laboratory, or at a commercially operating plant, this experimental tank is set on rack or trestle about 18 in. above the floor for convenience in making bottom connections and drawing off the charge.

The adaptation of Parral tanks for oil flotation in commercial operation is the subject of a pamphlet recently issued by the Parral System of Tank Agitation (Mr. Bernard MacDonald, manager), I. W. Hellman Building, Los Angeles, Cal.

Selenium.—The demand for selenium in 1915 fell off considerably, owing to absence of buying orders for railroad signal lamps and the curtailment of foreign export. The copper refineries have decreased their production somewhat, and in some cases the method of production has been changed. The price has ranged from \$2 to \$5 per pound.

Industrial Notes

Hearing on Dyestuffs Tariff.—Chairman Kitchen announced on Jan. 10 that the House Ways and Means Committee would begin hearings Jan. 14 on Representative Hill's bill proposing protective import duties on dyestuffs and certain chemicals, with a view to protecting and building up a domestic dyestuff industry.

Messrs. Eimer and Amend will erect a new building adjoining their present one at Eighteenth Street and Third Avenue, New York, to take care of their increasing business.

The Supplee-Biddle Hardware Company, Philadelphia, Pa., has increased the capacity of its Monel metal-casting foundry, to take care of its increased business.

The Wilson-Maculen Company of New York, pyrometer manufacturers, have moved to their new factory at Wales Avenue and East 142nd Street. The office and laboratory are also at the new address.

The H. W. Caldwell & Son Co. of Chicago announces the opening, on Jan. 1, 1916, of a sales and engineering office at 711 Main Street, Dallas, Tex., in charge of Mr. J. C. Van Arsdell.

The Edison Portland Cement Company, whose factory is at Stewartville, N. J., will resume operations in the spring. New machinery and improvements to cost \$200,000 have been authorized and will be completed by that time.

Disc Crushers.—Chalmers & Williams of Chicago Heights, Ill., have furnished one 48-in. Symons disc crusher to the Nevada Consolidated Copper Co. and one to the American Smelting & Refining Company at Hayden, Arizona.

The Armstrong Cork Company of Pittsburgh, Pa., has issued another edition of their corkboard catalog entitled "Nonpareil Corkboard Insulation." This book contains much information of value to anyone interested in heat insulating materials for low and moderate temperatures.

Duriron.—The Duriron Castings Co. of New York City has sent us a very attractive little concentrating dish, made of acid-proof duriron, which may be used as an ash receiver, but on the desk of chemical and metallurgical engineers will undoubtedly excite the curiosity of the owner to try it out as to the claims made for the non-corrosibility of duriron under trying conditions.

The new plant of the **Federal Dyestuff & Chemical Co.** at Kingsport, Tenn., is being pushed to completion as rapidly as possible. A site of 200 acres was donated by the Kingsport Development Co.

The November number of **The Labor Saver**, the little booklet issued by the Stephens-Adamson Mfg. Co. of Aurora, Ill., contains some interesting illustrated descriptions of coal handling machinery.

The Wellman-Seaver-Morgan Company, Cleveland, Ohio, has received contracts for four gas producers, together with a producer building and coal and ash-handling machinery for the Imperial Steel Works of Japan.

An **Industrial Exposition** will be held in Dayton, Ohio, Jan. 14 to 22, 1916. The exhibit will be held in the excellent new Delco building of the Dayton Engineering Laboratories Company. There will be ten exhibits, including automobiles, machinery, building materials, electricity, flowers, food, mercantile, advertising, business appliances and municipal shows. The object is to display goods made in Dayton.

Increasing Use of Aluminium.—The Nordyke & Macmon Co. of Indianapolis created a sensation at the

recent Automobile Show in New York by showing a car with engine cylinders and crank case cast integral in one light, sturdy block of aluminum. Aluminum pistons are also used. The extensive use of aluminum castings in this car has resulted in a reduction of weight by 1000 lb.

Substitution of Copper for Aluminium.—Some companies have found it profitable to substitute copper wire for aluminum conductors in their transmission lines, in view of the high price which can be obtained for the aluminum.

Aluminium and Bauxite.—Information on the aluminium industry of the United States in 1914 is contained in Bulletin No. 7, Part 1, of the Mineral Resources of the United States. Production statistics, consumption, imports, uses and methods of manufacture are included. The author is Mr. W. C. Phalen.

The Donora zinc plant of the American Steel & Wire Co. commenced producing sulphuric acid on Dec. 23. When the entire plant is completed it will contain ten furnaces with an output of 40,000 tons of spelter and 100,000 tons of commercial sulphuric acid per year. The acid plant is a three-unit plant, each unit comprising a tower, chamber and two roasting furnaces.

The Davison Chemical Corporation has been organized to take over all of the assets of the Davison Chemical Company of Baltimore, Md., large makers of sulphuric acid and fertilizer. Additions to the plant are being made which will give it an output of 300,000 tons of acid per annum. An acidulating plant is also under construction which will have a capacity of 300,000 tons of acid phosphate per annum. It is expected that this plant will be completed by the middle of next summer.

The Morse Bros. Machinery & Supply Co. have purchased the entire plant of the Kuenzel Process Smelter located at Buena Vista, Colo., and will dismantle and ship to Denver. This plant was never completed and only parts of it were in operation at all. A complete power plant of high pressure boilers, engines, blowers, compressors, crushing plant, machine shop. Fire and boiler feed pumps, shafting elevators, etc.

The Mineral Products Corporation, which started at the end of 1915 the successful production of potash from Utah alunite, is so much pleased with the results so far obtained that it intends to double the capacity of its Marysville plant in the near future. It is expected that the contract for this extension will be let to Westinghouse, Church, Kerr & Co. Mr. Howard F. Chappell is the president of the company. The vice-presidents are Mr. C. H. Macdowell, representing the Armour interests, and Mr. S. J. Jennings, representing the United States Smelting Co., while Mr. R. B. Forsythe is general manager of the mine and the plant.

The Buffalo Potash and Cement Corporation has been formed to erect a plant with a capacity of 20 tons of potassium salts per day with a simultaneous daily production of 750 barrels of cement. It is expected that the first unit of the plant, producing 10 tons of potassium salts per day, will be in operation in April, 1916. The Ruggles-Coles Engineering Company has undertaken the construction of the plant and supervision of installation. Mr. William B. Ruggles is a member of the board of directors of the Buffalo Potash & Cement Corporation.

To Authorize Exploration.—A bill designed to authorize exploration for coal, phosphate, oil, gas, potassium and sodium in public lands, and to provide for its disposition, will come before the House this week. The bill is a committee measure.

Mineral Production.—The value of the mineral production of the United States in 1914, according to the

Geological Survey, was \$2,114,946,024, being exceeded only by 1913 and 1912.

Sulphuric Acid in 1915.—The estimated production for 1915 of 50, 60 and 66-deg. acid is 4,007,000 tons, expressed in terms of 50-deg. strength, according to the Geological Survey. In addition there was a production of nearly 49,000 tons of fuming acid and oleum. These figures include by-product acid produced at copper and zinc smelters amounting to 952,000 tons of 60-deg. acid. This is an increase of 25 per cent over 1914. The prices were much higher than in 1914, and consequently the total value will be far in excess of the previous year.

Large Petroleum Production in 1915.—According to the Geological Survey the marketed production of petroleum in the United States in 1915 approximated 267,400,000 barrels, and the total yield approximated 291,400,000 barrels, about 24,000,000 barrels being placed in field storage. The increase is accounted for by the continued output of oil in large quantities from Oklahoma, Texas and Louisiana.

Increased Arsenic Production.—The estimated production of white arsenic for the year 1915, according to the Geological Survey, was 5,195 tons (of 2000 lb.), with a value at the smelter of 2 cents a pound. The estimate is based on the known production for the first ten months and the probable output for November and December. This output is an increase of more than 11 per cent over the 1914 production and 65 per cent over the 1913 production. The demand is far below the possible production, which could probably be made three or four times the present output if prices were sufficiently high.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in August, 1915, was 63. The total quantity of ore milled during that period was 2,478,267 tons. There were 9955 stamps in operation, with an average duty of 9.42 tons per 24 hr. Tube-mills in commission numbered 321. The yield for the month was 778,763 fine ounces gold. The tonnage treated and the yield of fine gold are the largest recorded this year.

Iron and Steel in Canada.—Bulletin 349 has been issued by the Department of Mines, Canada, containing information on Canadian production of iron and steel in 1914.

Electrothermic Smelting of Iron Ores in Sweden is the title of an illustrated bulletin, No. 344, just issued by Dr. Alfred Stansfield for the Canadian Department of Mines, Ottawa, Canada.

Copper in Arizona.—Market conditions resulting from the European war lessened the output of copper in Arizona from 407,923,402 lb. in 1913 to 393,017,400 lb. in 1914, according to the U. S. Geological Survey. Nevertheless, Arizona continued to be the leading copper-producing State.

Coal Mining in Illinois.—The growth of the industry in this State, the development of methods of mining and the present mining practice and markets are given in Bulletin 13, published by the Illinois Coal Mining Investigations, Urbana, Ill. The author is Mr. S. O. Andros.

Platinum in Spain.—The discovery of platinum in Spain was announced in an address made by Professor Orueta before the Society of Civil Engineers of Spain. Professor Orueta made an examination of the Ronda Mountain for the Institute Geologico (Geological Society) and found rich and extensive deposits. A Royal Decree has been announced reserving this district within certain boundaries to the State for a limited period for scientific investigation.

Mineral Resources of California.—The California State Mining Bureau is preparing a new general report of all of the mineral resources of California, under the direction of State Mineralogist Fletcher Hamilton. Instead of delaying publication until the entire area of the State has been covered the reports are being issued as advance chapters, by groups of adjacent counties, as soon as complete by the field men. All mines, quarries, mineral springs, cement mills and other plants handling mineral products are listed and described. The chapters already issued may be obtained upon application to the State Mining Bureau, Ferry Building, San Francisco.

Hydroelectric Development and Nitrogen.—In a talk recently given before the Commercial Club of Boise, Idaho, Mr. Henry J. Pierce of Seattle, Wash., said that the United States imported during 1913, about 625,000 tons of Chilean nitrate, valued at \$21,000,000, upon which the Chilean export duty was 60 per cent. The United States thus paid to the Chilean government \$12,600,000, which may be considered merely a part of the amount which the people of the United States pay for its policy of water-power stagnation. In other words, the people of this country would be quite as well off as they now are if they granted a subsidy or bonus of \$12,600,000 per annum for the establishment of the water-power nitrogen industry in the United States. In Europe over 1,200,000 water-hp. is used.

Obituary

Richard Henry Lee, superintendent of the Lebanon blast furnaces of the Pennsylvania Steel Company, died suddenly on Dec. 8, 1915. Mr. Lee received his education at Lehigh University, and upon leaving there was placed in charge of the cold blast charcoal furnaces of the Logan Iron & Steel Company at Burnham and Greenwood Furnace, Pa. He became general superintendent of the Logan company in 1891, and was assistant general superintendent of the Colorado Fuel & Iron Company from 1899-1903. He was connected with a number of other companies, and in 1906 became associated with the Pennsylvania Steel Company, taking charge of the Lebanon furnaces. Mr. Lee was also consulting engineer for the American Manganese Manufacturing Company in 1914-1915. He was noted for giving freely to others the benefit of his technical knowledge, and he was a frequent contributor to the American Institute of Mining Engineers and to the technical press. His last contribution to technical literature was published in the issue of Dec. 1, 1915, of METALLURGICAL AND CHEMICAL ENGINEERING (page 882), when he discussed the use of wet ores in charcoal blast furnaces. He made many warm friends in his numerous positions. He was a member of the American Iron and Steel Institute, the American Institute of Mining Engineers, and the Engineers' Society of Western Pennsylvania.

T. L. Willson, who took a prominent part in the early development of the calcium-carbide industry, is dead at New York City. Mr. Willson began his engineering work in 1880, when he constructed an arc outfit used for street lighting at Hamilton Ont., Canada. While the principal work which led to the foundation of the calcium-carbide industry, and in which he very actively participated, was done in North Carolina, Mr. Willson lived later many years in Canada and was interested in many undertakings besides calcium-carbide and acetylene. Until two years ago Mr. Willson was president of the International Marine Signal Company. Since that time he had devoted his entire attention to a new process for producing nitrogenous fertilizers from the air.

Personal

Mr. Edgar Baruch, chairman of the Southern California Section of the American Chemical Society, was re-elected a director of the Chamber of Mines and Oil of Los Angeles, Cal., at the annual meeting on Dec. 16.

Mr. Charles A. Chase has moved his Denver office from the First National Bank Building to 812 Cooper Building.

Prof. G. H. Clevenger of Leland Stanford, Jr., University attended the Pan-American Congress in Washington, and before his return to the Pacific Coast he was a few days in New York City.

Mr. E. H. Hamilton, formerly manager of the Virginia Smelting Co., has become consulting metallurgist to the Consolidated Mining and Smelting Co., Ltd.

Mr. Elwood Hendrick, who will be remembered as secretary and manager of the Albany Aniline and Chemical Works back in the early eighties, but more recently as editor of *The Percolator* and as vice-president of the Chemists' Club for several years, has left Wall Street. He has retired from his connection with Messrs. Denny, Pomroy & Co. of the New York Stock Exchange, with a view to addressing himself to literary work. We are very glad, indeed, to state that Mr. Hendrick has accepted the invitation to become a regular contributor to this journal.

Mr. James M. Hyde expects to move from San Francisco to Denver within a month, and make his future headquarters in the latter city.

Mr. R. E. Howe, formerly chief chemist for the Anaconda Copper Mining Co., has been promoted to be assistant superintendent of the converter department. He is succeeded by the former assistant chemist, Pierce Barker.

Dr. R. A. Kocher, chief chemist of the Pacific Chemical Wood Products Co. of San Francisco, was recently in New York City and the Eastern cities.

Mr. J. H. Mackenzie will become president of the Alaska-Treadwell on Jan. 1. He will be succeeded as consulting engineer by P. R. Bradley, who has been general superintendent. The latter position will now be filled by Russell Wayland.

Mr. Stuart B. Marshall, who has been connected with the Dunbar Furnace Company for 21 years, has severed his connection with that company to take charge of the property of the Aluminum Company of America at Whitney, N. C. This plant was recently acquired from the Southern Aluminum Co. and the works and immense dams are being completed. A new town, to be called Badin, is also under construction.

Mr. Thomas C. Oliver, manager of the Chemical Construction Co., Charlotte, N. C., was married on Jan. 5 to Miss Catherine Hill of Austin, Tex. Mr. Oliver spent some years as a mining engineer in the West before becoming associated with the Chemical Construction Co.

Mr. Thomas T. Read, who a few years ago, as the New York editorial representative of the *Mining Press* and as the very active secretary of the New York Section of the American Institute of Mining Engineers, made many friends in New York, has joined the staff of the New Jersey Zinc Co. in New York City.

Mr. R. W. Schultz, who as mill superintendent for the Mond Nickel Co., Ltd., of Conniston, Ontario, has had charge of extensive experimenting in the concentration of the copper-nickel ores of the Sudbury district, has resigned, having completed this work with entire success. He is spending several weeks at his home in Ravenna, Ohio.

Mr. B. B. Thayer expects to sail for Chile about Jan. 15, where he will spend about a month.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Aqueous Bath Apparatus

(Continued)

384,806, June 19, 1888, William W. White of Waterbury, Conn., assignor to Rogers & Brothers of same place.

Relates to a rack for supporting such articles as spoons, forks, etc., that are subjected to unequal wear, and require extra thick deposits on certain spots. The rack consists of two parallel rods suitably supported, and a third rod rotatable about its longitudinal axis, the third rod is supported upon the supports of the first rods. The third rod is provided with a plurality of spaced transverse flat wire springs the ends of which are connected by a chain. The third rod with springs and chain are folded back, the spoons, etc., placed across the first parallel rods so as to lie between the flat springs, the third rod and springs are then folded down and secured so that the chain engages and holds each spoon, etc., in place, and the frame supported over the plating tank so that the spots to be plated extra heavy will receive the desired deposit. The spoons, etc., are then removed and plated entirely. Or the plating process may be reversed, the spot plating being applied last.

414,860, Nov. 12, 1889, William A. Dunlap of Pittsburgh, Pa.

Relates to racks for supporting articles to be electroplated. The rack consists of a clamp made of a continuous rod or stiff wire, bent U-shape with preferably a coil at the bend. The long parallel arms are provided with a plurality of transverse rods projecting toward each other, which support an article to be plated. The arms are held together by a link or clasp. It is especially designed for such articles as screw-threaded caps for tin boxes.

441,892, Dec. 2, 1890, William J. Possons of Cleveland, Ohio, assignor to The Brush Electric Company of same place.

Relates to clamps for holding arc light carbons while being electroplated. The clamp may be described as a tubular clamp divided longitudinally into two parts which are hinged together, and which are provided with a spring to force the jaws into engagement with the carbon. The clamp is provided with an insulated metal contact and contact spring which electrically cuts out a clamp when not supporting a carbon, thereby preventing an open circuit among carbons which are connected in series. The patent refers to a copending application which became patent No. 441,894.

441,894, Dec. 2, 1890, William J. Possons of Cleveland, Ohio, assignor to The Brush Electric Company of same place.

Relates to an apparatus for distributing, supporting and electroplating a large number of arc light carbons at one operation. The carbons are quickly sorted on a subdivided tray, which upon inverting, discharges the carbons into a bank of tubular holders, the latter being quickly filled. A plurality of carbon clamps, such as described in his patent 441,892, are mounted upon a support, and placed over the projecting ends of the carbons in the bank of tubular holders, whereby the carbons are taken up by the clamps. The clamped carbons are next immersed in a tray of separate electrolytic cells wherein they are electroplated. The patent should be consulted for details.

459,838, Sept. 22, 1891, Edward S. Hayden of Waterbury, Conn.

Relates to a siphon to automatically maintain the level of the electrolyte in a tank, constant. It consists of a U-tube having one arm longer than the other, and an opening in the outer wall of the bend opposite the short arm. The siphon is secured in the side wall of the tank, with the long arm outside, in such a manner that the small opening is below the top of the tank. If the tank became too full, the excess liquid would cover the small hole, and the siphon would thereupon automatically remove the excess solution. After the hole became uncovered, the siphon would act as an overflow spout until the level of the solution reached that of the lower wall of the bend.

469,538, Feb. 23, 1892, Alexander D. Buchanan of Long Island City, N. Y.

Relates to a process of and apparatus for electroplating the iron hulls of vessels. The vessel is floated into a dock and over a collapsible flexible envelop which has been dropped to the floor of the dock. The vessel is supported upon a suitable keel-base, and by side braces, and is then thoroughly cleaned by scratch brushes, etc. A pickle of weak acid is then supplied to the flexible envelop which is raised to surround the ship, and the cleaning process completed. The pickle is then withdrawn and an alkaline copper plating solution supplied to the envelop, the iron hull being connected as cathode, and using an anode of copper links connected together, each link supporting one or more large insulating washers. As the level of the electrolyte in the envelop is raised, workmen scrape the iron just above the level to insure a deposit of copper taking place. After a deposit with alkaline electrolyte has been effected the ordinary copper sulphate bath is substituted.

479,557, July 26, 1892, Edward A. Clark of Boston, Mass.

Is for a toy consisting of a small electroplating outfit, made up of two small cells of battery in a case, the latter supporting a cell for the electrolyte. Binding posts are connected to the battery, to which wires for the anode and cathode may be connected.

496,597, May 2, 1893, Seth C. Catlin of Bloomfield, N. J., assignor to Emma F. Catlin of same place.

Relates to an apparatus for supporting articles to be electroplated, and consists of two wooden frames hinged together, preferably with rawhide, each frame being covered with a layer of muslin or canvas, so that the articles to be plated are inclosed therein. A number of hooks within each frame electrically connected to outer suspension hooks, provide means to support the articles.

497,129, May 9, 1893, Albert Roper Reams of Elmira, Cal.

Relates to a cabinet for holding the electroplating battery, various electrolytes and cleaning solutions, also a lamp or other heating apparatus to suitably heat the necessary liquids. The zinc of the battery is suspended from a pulley and may be raised or lowered as desired to vary the current strength.

498,707, May 30, 1893, Thomas S. Crane of East Orange, N. J.

Relates to an apparatus for coating the iron hulls of vessels, and consists of detachable open-sided flat receptacles for holding the electrolyte, the receptacles being held to the sides of the ship by suitable frames which in turn are held in any desired place by electromagnets. The hull of the ship is electroplated in sections, the joints of the several sections overlapping. The patent should be consulted for details.

501,996, July 25, 1893, Stephen H. Emmens of London, England.

Relates to an apparatus for electro-refining pig iron, and consists of a lead-lined steel tank, in which are placed insulating linings of ebontite, etc., the linings providing receptacles at the bottom to collect anode slimes and cathode powder or flakes. As anodes, the ordinary bars of pig iron, as produced by the foundries, are used. These are suspended by hooks from notched anode bus-bars above the cells on each side. The cathodes consist of a plurality of bars of malleable iron. The electrolyte is a nearly saturated solution of ammonium sulphate, covered with a layer of paraffin oil to prevent oxidation. A voltage of from three to four volts is used, and a current of about one-twentieth of an ampere per square inch of active cathode surface.

Book Reviews

Experimental Organic Chemistry. By James F. Norris, Ph.D. $5\frac{1}{2} \times 8$ in., 215 pages; price, \$1.25 net. New York and London: McGraw-Hill Book Co., Inc.

A skillfully written laboratory guide, which ought to enthrall as well as instruct the student. The directions, cautions and precautions, are minute and accompanied by the reasons—a most gratifying style of scientific writing intended for the instruction of students. The tests and experiments chosen are mostly those concerned with very common organic materials, such as fats, soaps, starches, sugars, etc., and thus the interest of the student is most securely held. The book is admirably conceived and executed.

* * *

Elementary Electricity and Magnetism. By Wm. S. Franklin and Barry MacNutt. 176 pages, 152 illus. Price \$1.25, New York. The Macmillan Company.

This is an elementary work on the fundamental phenomena in electricity and magnetism, presented from the standpoint of electromechanics, and thus concerned more particularly with results than the exact nature of the physical causes. The five chapters deal respectively with the magnetic effects of electric currents, chemical effects of electric currents, heating effects, induced e.m.f., and electric charges and condensers; appended to each chapter are several practical problems, with answers.

This book is essentially for the beginner and is made interesting by frequent happy allusions to the practical or useful aspects of the phenomena described, which are very clearly presented.

* * *

Food Analysis. Typical Methods and the Interpretation of Results. By A. G. Woodman. $8 \times 5\frac{1}{2}$ in., $x + 510$ pages, 107 illustrations. Price, \$3.00 net. New York: McGraw-Hill Book Co., Inc.

One of the books of the International Chemical Series, edited by Professor Talbot of the Massachusetts Institute of Technology, this is written by the associate professor of food analysis at that institution. It is intended for students' use, certain typical foods being selected for analysis, more because of the methods of analysis which they illustrate than because of economic importance. The book is, therefore, not a complete compendium of specific methods of analysis of every important food. Particular emphasis is laid on the interpretation of the analyses so as to judge of the practical values of the foods tested. Three general chapters treat of methods of manipulation, use of the microscope, examination for food colors and preservatives; after these milk, oil, butter, etc., are taken up in separate chapters. It is a practical and valuable book. The fine quality of paper used by the printers is especially commendable, over 500 pages (270 sheets) being only three-quarters of an inch thick, and yet of excellent opacity.

Shall the United States Be Self-Contained?

With so large a part of the world at war, even those at peace are beginning to feel unsafe. With passions aroused to fever heat there is no telling in many people's minds when, where and how the powers of wrath may rise against us; and the shocking comparison has been made of the present position of the United States with that of a very respectable old lady who goes out into the night with her hundred dollars safely tucked away in her stocking, little dreaming that even her legs are not immune and that there are prowlers at large who are without a sense of propriety.

This fear of an aggression of this country from the outside may or may not be purely psychological; its basis of reality may or may not be congruous to the intensity of the unsafe feeling. Yet the fact remains that the industries of this country while in peace with the outside world have been hit hard in many points by the European war, and the further eminently significant fact remains that those points where the country has been hit hardest are also the very points where it would be most vulnerable in case of war. For an army and a navy are useless without the means to maintain them, and the means consist largely in the self-containedness to meet a situation of war—and this very self-containedness has now been found wanting while this country is at peace. Time was when bows and arrows and swords and shields were the chief equipment of men at arms. At present without a great and complete chemical and metallurgical industry that supports itself in times of peace and can switch over to making war materials when called upon to do so, a nation is vulnerable in war and unprepared for peace. Strange it is, but true, that the making of dye-stuffs and of munitions of war are closely interlocked.

It is fair to say that upon the readers of METALLURGICAL and CHEMICAL ENGINEERING a large part of the ability of this country to defend itself rests. Without highly and completely developed chemical and metallurgical industries neither the army nor the navy could hold its own if we were attacked. Bearing in mind all that has been said of that phase of economics which has to do with the taxation of imports, the facts remain that as things are, the self-containedness of this country is greatly dependent upon these industries, and also that, as things are, these industries cannot hold in this country if no import duties are applied. This does not mean that everything chemical and metallurgical should be protected and that manufacturers should be allowed to write their ambitions for profit into the revenue statutes. This would beget as great an evil as the other extreme.

One of the difficulties of the tariff in the past has been that we have had to treat it as though it were a case in court and but one of only two solutions of its many problems were possible—to determine whether it be generally high or generally low. This seems about all that we have been able to do. The congressman we have voted for may have been familiar with our affairs and anxious to help us, but has had little power to do so. He took his place at his desk like a good little boy at school and voted for the party leader as speaker of the House. The speaker named the committees and allotted membership in each—according to geography. If manufacturers were in trouble at their works, and needed an engineer to help them out, they would not want for that purpose a lawyer from a distant state, selected for geographical reasons. And yet that is about as near as they have been able to reach the question what import duty the Government should charge on the merchandise that they produce. The Congressman's advice might have been good in a case at court, but he has been a rare bird indeed if he could get the chemical situation into his head. It was not his fault: in minor part it was due to his lack of time and training. In major part it was the manufacturer's fault.

When a tariff bill has been introduced, manufacturers—from the chemical and metallurgical fields as well as from others—have been likely to flock to Washington and crowd over each other and lobby and interview and appear at hearings and claim all that they dared ask for. The members of the Committee on Ways and Means have usually been helpless. They could not have heard all that was offered them if they had had ears all over their heads in the place of hair. And if they had had this monstrous endowment they could not have remembered what they heard. And if they could have remembered it they could not have correlated it and brought it into form and into the semblance of truth. For in the past all the time the manufacturers have been contradicting each other. The one using the finished product of another as one of his raw materials wanted that product free. The man making it wanted a dollar a pound duty imposed, but he wanted his raw materials, the intermediates, free. The intermediate man made a similar plea for his product and the man back of him did likewise, all uttering the same cry, but calling for a different law. This is somewhat overdrawn, nevertheless it is a caricature of something that has been real. No wonder it is said congressmen have taken to drink. And the result of it all has been that the United States has never had a good, well constructed, suitable tariff law.

Yet two bright rays fall into this dark-in-dark picture. It is a picture of the past. The future may be different. In its present troubles this country has learned something. The manufacturers have learned something, and the Government has learned something. How much the manufacturers have learned became manifest at the hearings before the House of Representatives Committee on Ways and Means on the Hill

bill for a dyestuff tariff last month, of which a full account may be found on page 125 of the present issue. It was not a series of pleadings of everyone for his own pocket. There was pretty general unanimity of opinion that the whole matter must be considered from a higher plane, in a co-ordinated manner, with this one principal leitmotiv: that this country shall be self-contained. For the part it has played in crystallizing this sentiment, the Chemical and Dyestuff Committee of the New York Section of the American Chemical Society and its chairman, Dr. Hesse, as well as the president of the national society, Dr. Herty, really deserve great credit.

The other ray of hope—and possibly the greater wonder of the two—is, of course, the reported conversion of the Administration to the necessity of a non-partisan permanent tariff commission. There was once such a commission. It went out after the Democrats came in. If it now comes back through the Democrats it is hard to see how any party can ever afford to let it go out again. There is good reason for rejoicing and to the Administration high praise is due for having the courage of freshly acquired conviction. But for the representatives of the chemical industries to think that now their task is ended would be a frightful and fatal mistake. The good work begun by the Chemical and Dyestuff Committee of the New York section of the American Chemical Society and by others needs to be continued, broadened, strengthened, intensified. The tariff commission—if it comes into existence—will need all the help and advice it can get from those thoroughly familiar with the technical details of all the industries. Let the chemical and metallurgical industries be in the front rank to render freely such service in co-operation.

And yet when all is done that is humanly possible for the chemists to do, more remains to be done. Dr. Baekeland was right when he said in his Perkin medal address (published in full on page 151 of this issue) that if we turn our present unparalleled chances of success for creating a great American chemical industry into a gigantic fiasco, the whole blame should not be placed on our chemists. Let Dr. Baekeland's address be read—broadcast throughout the land—by our business men, captains of industry, and lawmakers. Let them understand that American chemists are striving not merely for themselves but for the self-containedness of the American nation.

The Future of Steel Prices

In the past dozen years there have been three high levels in steel prices, in 1907, at the close of 1909, and at the close of 1912. The present average of finished steel prices, not for prompt shipment but for shipment at mill convenience, is about \$2 a net ton above the first high point, \$6 to \$7 above the second and about \$8 above the third. It required a period of about two years, with continued heavy demand and mills working at high pressure, to develop the high level of 1907. The present level has been reached in thirteen months, and two-thirds of the total advance has occurred in the past four months of the thirteen.

Clearly the steel market has passed entirely beyond its ordinary bounds, as established by the precedents of a dozen years, and yet prices still show a rising tendency. The natural inference is that eventually the readjustment will come, that prices will fall. Meanwhile, however, new conditions may be established whereby prices may not fall to the preceding low levels. It is certainly important to consider the probable bearing of such new conditions as we see being established at present, or can foresee as likely to develop.

In the iron and steel industry great changes in processes of manufacture occur in a few years. Truly wonderful economies have been introduced, but these do not show in prices quoted in money. In terms of money, steel sold at its lowest prices in 1897 and 1898. In terms of mental and manual effort expended and intrinsic value of raw material and equipment used, steel is to-day produced at very much lower cost than at that time. For instance, wages per hour are very much higher while in addition the mental and manual effort per hour of the workman is undoubtedly decidedly less. Again, the intrinsic value of the ore used is very much less than formerly, the iron content being lower and the material to be fluxed off, involving additional consumption of limestone and coke, is much greater. For another of many illustrations that could be given, the equipment used, while costing much more, is produced by the builders at much lower cost, measured in terms of mental and manual effort expended in its building, and in its efficiency for the purpose, than formerly. If the iron and steel industry were given to-day the same raw materials and the same wage rates and labor performance as in 1897, combined with present practice and equipment produced with the same low-priced labor, it would be able with such a combination to sell steel at astonishingly low prices.

While improvement in processes and equipment is bound to continue, it cannot be expected that progress can be so rapid in future as in the earlier years. The curve representing cost of production in terms of effort expended and consumption of material cannot become tangent to the line of perfection, but it has some of the characteristics of an asymptote. It seems reasonable to conclude therefore that the future of steel prices, measured in terms of money, will hinge more upon economic conditions than upon technical progress.

Sweeping changes have been brought about in economic conditions by the war, and probably still greater changes are to occur in the future. For decades the iron and steel industry has been supplied with labor chiefly through immigration. There have been successive changes in the source of the immigration, until in recent years it has been chiefly Croatian, Slavonian, Italian, Magyar, Polish, Roumanian, Russian, Ruthenian and Slovak. Prior to the war there had been noted a tendency in this immigration to decrease relative to the requirements of the industry. Economic conditions resulting caused wages in the iron and steel industry to rise somewhat more rapidly than the general wage level of the country. Early in 1913 the industry made a general wage advance at a time when there was no corre-

sponding general advance in wages. The war has caused immigration almost to cease, and this change has affected the iron industry much more than it has affected industries in general. The net change in the population of the United States occasioned by people entering and leaving the country was an increase of 754,205 in the fiscal year 1913 and an increase of 687,065 in the fiscal year 1914, making an average increase of 60,000 per month. From July 1, 1914, to Dec. 1, 1915, the net increase was 124,033, or 7300 per month. Thus the war has been causing a deficiency to accumulate in our population at the rate of 52,700 per month or 630,000 per year, and this loss bears much more upon the iron and steel industry than it does upon industries in general. At the present time a general advance in wages is being made in the iron and steel industry, at a time when wages in industries as a whole are not being specifically advanced.

One can scarcely conjecture what will occur with respect to immigration when the war closes. One does not even know what the conditions will be, how seriously territory has been or will be ravaged, what effort would be required to restore it, and what power there will be to make the effort. The balance of probability appears to be that there will be no large immigration, or at any rate such as would make up for the deficiency now accumulating and for the industrial expansion now in progress in the United States. The steel industry, therefore, seems to face for the future distinctly higher wage rates, relative to those which may prevail in industries generally, than in the past. Measured in commodity values steel should, therefore, be expected to sell at higher rates than in the past.

We are accustomed to seeing commodity values and security values move together. When credit is readily obtained the value of both securities and commodities tends to advance, and when credit conditions are strained the reverse occurs. The war tends to divorce these trends from each other. It occasions both a great destruction of commodities and a great deal of borrowing. At the close of the war the demand for commodities will be out of proportion to the ability to borrow. Commodities will tend to be higher in price than normal relative to the value of securities. The demand for commodities that can be paid for in current effort, pay as you go, will be greater than the demand for commodities that are to be paid for with credit, by the flotation of securities. Steel falls more in the latter category than in the former, and in this respect it will be at a disadvantage. Man will have to make the effort to build up a greater credit structure than has ever existed before. How successful the effort may be remains to be seen, but there will be the foundation that has been lacking for many years, the certainty that there will not be a great war for a long time at least. For many years past a distinct element of timidity has been observable in capital abroad, ascribed openly to the fear of a continental war. If the credit structure can be built up, then all the elements will be present for higher prices for steel, relative to commodities in general, than have prevailed hitherto.

Hydrometallurgy of Zinc and Lead

Electrolytic Zinc at Bully Hill

To the Editor of Metallurgical & Chemical Engineering:

SIR:—I wish to be allowed to correct what seem to me some slightly inaccurate statements of Messrs. Lyon, Ralston and Cullen in your issue of Jan. 1, page 30, in their article on "Hydrometallurgy of Zinc and Lead," regarding zinc processes, more especially as practised at Bully Hill, Cal.

Some two years of conscientious effort were expended in the development of the zinc hydrate process described, and excellent zinc cathodes were made during a fair share of this period.

It also appeared that zinc could be made by this process at a cost which would make commercially possible the production of from 10 to 20 tons of zinc per day at Bully Hill.

Both the Bully Hill Company and the General Electric Company, the owners of the Bully Hill property, however, were quite as much interested in the development of a generally and widely applicable process, and they finally concluded that the zinc hydrate process could not compete to advantage in the Montana, Utah, Idaho district, e. g., which the writer considered the most promising one in the country, and other important districts.

As a result, the zinc hydrate process was set aside for the time, and substantially a method that was earlier tried with some success, but with modifications, was reverted to, viz., direct electrolysis of zinc sulphate with regeneration of acid, and this has been since continued.

The revised process was planned out in October and November, 1914, was put in practice in March, 1915, and has been producing 300 to 400 lb. of zinc per day most of the time since then—practically the full capacity of the experimental plant.

During this period the only raw materials entering the plant, aside from materials of construction, etc., have been fuel oil for roasting and melting zinc. More than enough acid is fixed in roasting to supply losses, and chemical reagents have been used for analytical purposes only.

The process, as it stands, is partly old, but was never before made commercial. The ways and means, mechanical and other, are perhaps new in detail. Certain very valuable results of the work are a wealth of collected data, intended to fix the approximate limits, as nearly as may be, between which profits can be produced under somewhat varying conditions with different zinc ores.

The authors of the article which attracted my attention state that the electrochemical zinc plant is extraordinarily expensive as an investment, as compared with the older retort process plant.

This is only true, I think, in any or the usual case, as the primary power station may be taken as a part of the electrochemical plant.

A completely equipped electrochemical zinc plant of 200 tons zinc per day capacity at Butte, Mont., including substation (but not primary generating plant), offices, laboratories, repair shops, etc., would cost, I estimate, between \$2,400,000 and \$2,600,000. These figures were

FIG. 1—OUTPUT OF BULLY HILL ELECTROLYTIC ZINC FOR TWO OR THREE WEEKS

FIG. 2—STATIONARY CATHODE DEPOSITS OF ELECTROLYTIC ZINC, 24 IN. X 36 IN.

worked out directly in considering the Butte & Superior Copper Company's property.

An equivalent retort process plant, including its roasters, pottery, etc., but not a sulphuric acid plant, would evidently cost \$2,800,000 to \$3,200,000, depending upon its location.

An electrochemical plant producing 10 tons of zinc per day would cost \$200,000 to \$300,000, depending upon location, etc. The former figure would cover a zinc plant auxiliary to a going smelter—the latter would be more nearly approached by a plant dependent upon its own repair shops, offices, laboratories, etc.—particularly if the roaster gases required special treatment before being released.

The writer does not believe that a retort plant of 10 tons of zinc per day capacity could be put in operation for particularly less than these figures. The operating costs would most evidently mount more rapidly with a decreasing production rate in the case of a retort plant than in the case of the electrochemical plant.

Messrs. Lyon, Ralston and Cullen may also mislead a little, I fear, when they state that "extraordinarily cheap" power is essential. Cheap power is likely to be essential, it is true, especially where no higher than a 60-per cent zinc concentrate is treated.

Butte-Superior concentrates, 55 per cent zinc, could easily carry a power rate of \$25 to \$30 per horsepower-year. Zinc ores with 25 per cent to 45 per cent zinc could carry somewhat higher power rates so long as the retort process continued to fix the value of zinc ores or zinc concentrates delivered to the electrochemical plant.

These power rates exceed American Niagara rates by 40 per cent to 65 per cent, and exceed Norwegian rates by some hundreds per cent.

What other electrochemical industry could afford \$25 to \$30 per horsepower-year in Montana in normal times and with normal Montana labor costs?

Ferrosilicon could not, except with 50 per cent alloy selling consistently at \$70 or better; calcium carbide might with a developed Western market; atmospheric

TABLE I—COSTS PER TON OF ZINC

	Retort Process, Oklahoma	Electro- chemical Process Butte, Montana
Plant capacity tons zinc per day	200	200
Cost per ton zinc:		
Salaries	\$1.25	\$0.93
Labor	11.30 (\$1.75 and \$2)	6.00 (\$3.50)
Gas at 4c.	2.93	
Coal at \$2.	1.67	
Power at \$26 hp. yr.	0.25	14.65
Clay	0.63	
Repairs and sundries	1.04	4.14
Fixed capital charges 16½ per cent first cost	\$18.82	\$25.72
	6.36	5.70
Total treatment cost	25.18	31.42
Freight on concentrate to Oklahoma	16.62	0.00
Freight to St. Louis on zinc	\$41.80	\$41.80
Freight to New York on zinc	7.20	2.60
		10.00
Treatment cost and freight per ton zinc:		
F.o.b. St. Louis		
F.o.b. New York	49.00	44.40
		41.42
Above figures neglect mining and milling costs to produce concentrates; also neglect relative recoveries of zinc values which would be:		
For retort process, say	87.0%	
For electrochemical process		
Correcting for relative recoveries, the relative treatment and freight costs on above basis would be about:		
For St. Louis delivery	\$44.40	\$37.06
For New York delivery	\$49.00	\$38.06
Equivalent cost per lb. zinc	2.45c.	2.22c.
		1.903c.
		1.853c.
Net value of silver, lead, copper in residues from Butte-Superior concentrate (26 oz. Ag.)	\$7.20	\$22.70

nitrogen fixation could not; aluminium could, were there any necessity for it.

That electrolytic zinc is commercially possible in Montana is indicated by the estimates in Table I, referred to above, made two years ago, and only revised slightly in the light of later knowledge and develop-

FIG. 3—ROTATING CATHODE DEPOSIT, 320 LB. (4 FT. DIAMETER, 1½ TO 2 R.P.M.)

FIG. 4—VIEW OF THE REVERSE SIDE OF THE SAME ROTATING CATHODE

ments. They indicate to the writer that it would be economically profitable to ship the Butte-Superior Company's product to market from Montana as spelter rather than to Oklahoma as concentrates.

TABLE II—ANALYSES

	Bully Hill Ore	Bully Hill Zinc
Zn	29.0	99.98
Fe	15.0	.0053
Cu	2.5	.0050
Cd	0.3	.0010
Pb	tr	tr
Pn	tr	none
S	31.0	
SiO ₂	6.0	
Al ₂ O ₃	8.0	
BaSO ₄	3.0	
CaO	2.5	
MnO	0.6	
MgO	2.8	

Herewith are a series of photographs of zinc deposits made at Bully Hill not especially selected; also analysis of Bully Hill representative ore and analysis of electrolytic zinc therefrom.

Hydrometallurgy of Lead

To the Editor of *Metallurgical & Chemical Engineering*:

SIR:—In your issue of Jan. 1, under the subhead of "Lead," of an article entitled "Hydrometallurgy of Zinc and Lead in 1915," by Messrs. Lyon, Ralston and Cullen, there is a description of a process for the extraction of lead from its ores by the use of a strong brine. It might appear to many that the development of this method was quite recent, while as a matter of fact it has been familiar to a number of us for some twenty-four years.

During the year 1892, while conducting my metallurgical testing laboratory in San Francisco, I developed a method for the treatment of some of the oxidized ores of the old Willow Creek Mine situated in Washoe County, Nevada. The ore contained about 10 per cent lead, nearly all of which was in the form of sulphate, the remainder being galena. The ore also contained about 10.0 oz. of silver per ton, none of which was soluble in a solution of thiosulphate of soda.

The solution used by me to treat this ore was made by adding 20 lb. of common salt and $\frac{1}{2}$ lb. of copper sulphate to every 100 lb. of water. This solution was placed in small wood vats and heated almost to the boiling point, at which time the dry ore which had been crushed through a 40-mesh screen was added, forming a mixture of about 1 to 1. This mixture was agitated by the injection of steam, which also sustained the temperature.

After agitating for about one hour the mixture of solution and pulp was diluted to about 4 to 1 with the plain hot salt solution without the copper sulphate, and then agitated again for a few minutes, when the pulp was allowed to settle and the clear solution on top drawn off, at which time more plain hot salt solution was added and the operation repeated, and finally giving the settled pulp a displacement wash by gravity with hot fresh water. The hot solution drawn from the vats was passed through cement copper to recover the silver and then through scrap iron to recover the lead and small amount of copper held in solution. The extraction on this ore was over 85 per cent of both the lead and silver.

Experiments were also made on some of the old concentrates which had been lying in the mill for years. They carried quite a percentage of sulphides and arsenic. They were therefore given an oxidizing roast and then treated by the above method with an extraction of only 45 to 50 per cent of the contained lead and silver.

The largest amount of ore that I treated by this method at one time was about 1 ton, and that lot was treated in Salt Lake City in 1900 to demonstrate to a party of men the feasibility of the method for the particular ore mentioned above, all former tests having been made on samples of from 1 oz. to 500 lb.

HENRY R. ELLIS.

Salt Lake City, Utah.

Will Silver Come Back?

To the Editor of *Metallurgical & Chemical Engineering*:

SIR:—An eminent European authority of international standing—Mr. Moreton Frewen—in a recent letter to the writer says:

"I anticipate that when the Bankers, after the War, have come to count its cost and the enormous mass of unconvertible paper that has been issued and most of which will be at a huge discount, they will take immediate steps to secure Open Mints and Free Exchanges for the two metals"—i.e., gold and silver.

In view of the increasing international scramble for the world's limited supply of gold (when compared with the business of the world), and the recent great flow of that metal from Europe to the United States in payment for food, raw materials and war supplies, all indications are that the European countries will, after the war, be absolutely driven by dire necessity to a greater recognition of silver as a money metal, which will have far-reaching effects on the world's trade and commerce and will enhance the market price of silver.

This will necessarily affect the United States as a great silver producer and exporter, and American trade with silver-using countries.

Unfortunately, matters of finance a little out of the usual course too often do not appeal to business men and others absorbed in their own affairs. They do not take the time to understand them and, not understanding them, conclude such matters are wrong. A proposal may be no novelty; it is only a novelty to them.

Moreover, years ago there was so much bitter controversy on the silver question that the moment a writer approaches it, even remotely, prejudice is aroused with many not fully informed and whose minds are not in possession of information on changed conditions.

Nevertheless, in view of apparently inevitable action by European countries in the not distant future, a brief resumé from an American standpoint on the subject of silver as affecting United States production and export of the metal and American trade and commerce with silver-using countries is opportune at this time.

The 1915 report of the director of the U. S. Mint contains much germane information furnishing food for thought.

UNITED STATES LEADING SILVER PRODUCER

While the United States has long been one of the leading producers of silver, the price of the metal has been practically fixed in London.

The 1915 mint report furnishes the following information:

The production of gold and silver from the mines of the United States, from 1792 to 1914 inclusive, is stated as:

TABLE I

	1913	1914
North America:		
United States	\$40,348,100	\$40,067,700
Canada	19,041,000	15,097,300
Mexico	42,705,100	89,089,200
	\$102,094,200	\$94,264,200
Central America	1,290,000	1,336,500
South America	7,328,600	7,155,000
Europe	9,215,500	8,448,400
Australasia	10,949,800	1,946,700
Asia	3,130,400	2,998,400
Africa	637,900	570,000
Total	\$135,246,400	\$116,719,200

Gold, 175,859,429 fine ounces; value, \$3,635,331,200.
Silver, 2,158,431,200 fine ounces; *commercial* value, \$1,749,585,300.

The sources and *commercial* value of the world's production of silver for 1913 and 1914 are given as follows, at \$0.604 per ounce for 1913 and at \$0.553 per ounce for 1914:

It is obvious that North America is especially interested in the future of silver.

MINTS CLOSED AGAINST COINAGE OF SILVER "ON PRIVATE ACCOUNT"

Space does not admit of details of the adoption of the single gold standard by various countries.

In 1873 the U. S. Congress passed an act whereby subsidiary U. S. silver coins and a "trade dollar" of 420 grains weight (in lieu of the previous standard silver dollar) coined at the expense of the depositor, i.e., "on private account," should thereafter be a legal tender at their nominal value for any amount not exceeding \$5 in any one payment.

In 1876 Congress took from the "trade dollar" its legal-tender quality and authorized the Secretary of the Treasury to limit its coinage to its demand for exportation. The coinage of this dollar (intended for use in trade with China and Japan) practically ceased in 1878, and its further issue was prohibited in 1887.

In 1878 Congress passed the Bland-Allison act, which directed the Secretary of the Treasury to purchase, at best rates possible, silver bullion to the amount of not more than \$4,000,000 worth nor less than \$2,000,000 worth per month, to have it coined into silver dollars of full legal-tender power and to issue certificates, receivable for any Government dues, upon the deposit of those coins in the Treasury. This act brought into circulation two new elements—silver dollars (the coinage of which had been prohibited since 1873) and the silver certificates.

In 1890 Congress passed an act providing for the purchase of 4,500,000 ounces of silver bullion each month and the issue in payment therefor of Treasury notes, and repealing so much of the act of 1878 as required the monthly purchase and coinage of silver bullion.

In 1893 Congress repealed the clause in the act of 1890 directing the purchase of silver bullion and the issue of Treasury notes therefor.

In 1893, also, the mints of India, with its 259,000,000 of silver-using people, were closed to the "free coinage" (i.e., on private account) of silver rupees. In other words, private parties were no longer permitted to take their silver bullion or personal ornaments to the mints of India and (subject to a small charge for the cost of coining) receive the equivalent in silver rupees.

CLOSED MINTS AUTOMATICALLY DEPRECIATE SILVER

The 1915 U. S. mint report reveals the following information:

Since 1873 the commercial ratio of silver to gold has more than doubled.

The commercial ratio of silver to gold for 186 years, i.e., from 1687 to and including 1872, was practically steady, the minimum for any one year (1760) being 14.14 and the maximum (1812) being 16.11.

From 1873 the ratio rose from 16.16 in that year to a maximum of 39.74 (1909), in 1914 being 37.49.

Since 1873 the gold value of an ounce of silver has declined more than 50 per cent.

The value per ounce of silver (1000 fine) in U. S. gold coin, based on the average price of bar silver in London, for the eighty-two years, from 1833 to 1914

inclusive, was practically steady, rising from \$1.297 in 1833 to a maximum of \$1.360 in 1859, and in 1873 was \$1.29769.

From 1873 it declined to a minimum of \$0.52016 in 1909, in 1914 being \$0.55312.

Since 1873 the bullion value of the silver dollar has declined more than 50 per cent.

The bullion value of the silver dollar (371¼ grains of pure silver) at the annual average price of silver each year from 1837, commenced in 1837 at \$1.009, attained its maximum of \$1.052 in 1859, and declined from \$1.00368 in 1873 to a minimum of \$0.40231 in 1909, in 1914 being \$0.42810.

WHAT BECOMES OF SILVER MINED IN UNITED STATES

The 1915 mint report furnishes interesting information of the use of U. S. silver in coinage, arts and manufactures and exports.

For the 122 years from 1793 to 1914 inclusive, the U. S. Government coined silver of the *coinage* value of \$506,234,355, the amount for 1913 and 1914 being stated as: 1913, \$3,184,229; 1914, \$6,083,823. No standard silver dollars have been coined since 1904.

The difference between the *commercial* value and the *coinage* value of the silver coined is called "seigniorage," and is the profit of the Government.

The stock of silver coin in the United States on June 30, 1915, is estimated at \$753,701,905, and the stock of silver bullion in U. S. mints and assay offices on June 30, 1915, at \$4,337,516.

For the thirty-five years from 1880 to 1914 inclusive, the amount of silver (U. S. coin, domestic and foreign bullion and foreign coin) furnished for use in manufactures and the arts amounted to 485,500,570 fine ounces.

The exports of silver bullion (presumably *commercial* value, though not so stated) from the United States from 1900 to 1914 inclusive are as follows:

United Kingdom	\$640,557,856
Asia	98,235,551
All Other Countries.....	61,702,956
	\$800,496,363

A great part of the silver exported from the United States to the United Kingdom is re-exported from London to the Orient, and the report gives the details of the enormous silver export, from 1881 to 1914 inclusive, from London to India, China and the Straits Settlements.

SILVER COINAGE BY FOREIGN COUNTRIES

The silver coinage of the world for 1913 and 1914 alone, when the average market price of silver per ounce was \$0.60458 for 1913 and \$0.55312 for 1914 (the *coinage* value calculated in U. S. money), was:

1913	\$131,125,727
1914	120,932,328

The ten leading countries (outside the United States) being as follows:

	1913	1914
Austria-Hungary	\$10,929,392	
China	15,829,272	\$19,419,143
France	4,179,250	
Germany	12,168,426	16,010,633
Great Britain	8,241,662	
India	55,551,112	17,608,768
Japan	2,138,127	
Netherlands	321,600	7,268,362
Persia	2,872,495	4,756,890
Russia	3,442,293	

For the fifteen years 1900-1914, during which the United States exported, as shown above, silver bullion to the amount of \$800,496,363, the market price of silver averaged less than 58 cents per ounce.

Foreign countries have made, in the aggregate, enor-

mous profits out of the "seigniorage" of coining cheap silver originating in the United States.

INDIA NOW GOLD "SINK HOLE"

The great majority of the 295,000,000 of people of India do not use banks as Americans do, from the wealthiest down to the poorest more or less hoarding their surplus coin, many people of small means having same made into bracelets, anklets, etc., for their wives, who thus become the family "safety deposits." Others hide their coin reserves, while the wealthier have secret strong rooms or receptacles for bullion and coin.

For fifty years prior to the closing in 1893 of the Indian mints to the coinage of rupees "on private account" the import of silver into India was four times that of gold, and India was known as the "sink hole" of silver, as that metal once gone into India practically never came out.

The change of standard in India in 1893 from silver to gold resulted in India's precious metal imports, from 1896 to 1910 inclusive, being in the proportion of 100 of gold against 64 of silver.

In 1910 the Indian Government imposed a 16 per cent duty on all silver bullion imported into India, resulting in increasing imports of gold (mostly for hoarding purposes) and declining imports of silver.

The annual statistics for the fiscal years 1873 to 1912 inclusive show the enormous excess of imports of gold and silver into India over the exports from India, the excess gold imports increasing at a rapid rate in recent years, from 1896 to 1914 inclusive, amounting to more than 27,000,000 ounces of gold of the value of more than \$540,000,000!

This abnormal Indian absorption and hoarding of gold has practically offset the benefit to the world's trade and commerce of the increased gold output of South Africa and elsewhere in recent years, and has materially intensified the gold shortage in Europe.

CHEAP SILVER ESPECIALLY BENEFITS THE ORIENT

Cheap silver especially benefits the great silver-using countries of China, India, Japan, etc., in their international trade with (and at the expense of) the gold-standard countries in Europe and the United States.

Kaiser William of Germany once referred to the Oriental nations as the "Yellow Peril." Cheap silver is developing them into a commercial and manufacturing "Yellow Peril" to the gold-standard countries of Europe and the United States.

Years ago it was predicted that, with the decline in the market price of silver, "the yellow man with the white dollar would beat the white man with the yellow dollar" in international trade and commerce. That prediction is being verified.

Cheap silver, involving fall in exchange between gold-standard countries and silver-using countries, is an increasing tariff in favor of the Asiatic producer and manufacturer, as against imports from gold-standard countries, but, unlike a tariff, Asiatic exports are not reduced, but are, so to speak, subsidized.

While India and Japan are nominally on a gold-standard basis, silver is the money metal of the great masses of the people. China is wholly on a silver basis.

Since the commencement in 1873 of the fall in the market price of silver, the rise in the rate of wages and cost of living in the great silver-using countries of the Orient has been inconsiderable.

The standard silver coins of those countries and their equivalent values in U. S. gold coin are: China, the "tael," about 55 cents; India, the "rupee," about 32 cents; Japan, the "yen," about 49 cents. Those coins have almost as great a purchasing power in the internal

trade and commerce of their respective countries today as they had years ago.

But in international trade between those countries and the gold-standard countries of Europe and the United States, cheap silver stimulates Asiatic factories and exports and fosters the competition of yellow labor with white in important trades—iron, coal, steel, textiles, etc.

The greater the amount of silver that Asiatic countries have had to pay for the purchase, on a gold basis, of imports from the gold-standard countries, the more the Asiatic countries were driven, in self defense, to manufacture for themselves wherever possible and cease importing to that extent.

Silver, as a mere commodity, without recognition at the mints of the world at any internationally fixed ratio with gold, naturally fluctuates in market price, and to that extent renders more difficult trade and commerce between the gold-standard countries of Europe and the United States and the populous silver-using countries of the Orient.

For instance, as the bullion price of silver falls, it becomes more difficult to continue exports to China. No merchant in China can buy exchange (in other words, buy gold) on London, Paris or New York, so that cheap silver assists Chinese mills and other manufacturing industries, protecting them from competition of imported foreign goods, which would be possible with higher-priced silver, and especially with an international-fixed ratio between silver and gold.

Cheap silver stimulates Asiatic exports to the markets of America and Europe for the simple reason that the Asiatic exporter who formerly sold his products for one British sovereign or for five U. S. gold dollars received in exchange for that sovereign or five gold dollars three "taels" only. With cheaper silver, he now receives for that British gold sovereign or five American gold dollars, not three, but eight "taels." The same general conditions prevail in India and Japan, and the great industrial development since 1873 in the silver-using countries is very largely owing to cheap silver.

With the opening of the Panama Canal and Japan's development of her mercantile marine in the Pacific, the gold-standard countries are confronted now, more than ever before, with the industrial menace of cheap silver—of "the yellow man with the white dollar."

All of which demonstrates that this country is vitally interested in any action found necessary by the European countries looking to the increased use of silver as a money metal, at some internationally fixed ratio of silver with gold, thereby permanently enhancing and steadying the future market price of silver to the great advantage of Europe and the United States, with corresponding impetus to international trade and commerce.

The consent and co-operation of the United States will be necessary to perfect any such action by the European countries.

THOMAS TONGE.

Denver, Col.

[In publishing Mr. Tonge's article we do not wish to commit this journal in any way on the political aspects of the question, but feel that the interesting and timely statistical information contained in Mr. Tonge's article merits the attention of silver producers and metallurgists in general.—Editor METALLURGICAL AND CHEMICAL ENGINEERING.]

Arizona Copper Strike Ended

The four months' labor strike at the Shannon Copper Company's, the Detroit Copper Company's, and the Arizona Copper Company's works in the Clifton and Morenci district in Arizona has been ended on Jan. 24.

The wages are increased. The union is not recognized. Any future differences are to be settled by conferences between company officials and employee committees.

There is to be an immediate resumption of mining, milling and smelting. The normal production is 6,000,000 lb. of copper monthly.

Mineral and Chemical Exploration Act Passed

The House of Representatives has passed an act "to authorize exploration for and disposition of coal, phosphate, oil, gas, potassium and sodium," reported favorably by the House Committee on Public Lands.

The measure has now gone to the Senate, where it has been referred to the Committee on Public Lands of that body.

Important features of the measure as it passed the House are as follows:

The Secretary of the Interior is authorized to lease to any qualified applicant any deposits of phosphates or phosphate rock belonging to the United States, through advertisement, competitive bidding or such other methods as the secretary may by general regulations adopt. Each lease shall be for not to exceed 2560 acres of land, the land to be in compact form, the length of which shall not exceed two and one-half times its width. For the privilege of mining, royalties, to be fixed by the secretary in advance of offering the land, are to be paid, not less than 2 per centum of the gross value of the output, and an annual rental, which shall not be less than 25 cents per acre for the first year, 50 cents for the second, third, fourth and fifth years, and \$1 per acre thereafter, the rental to be credited against the royalties. Leases are to be for indeterminate periods upon condition of a minimum annual production. There is a strike clause, and there is to be a readjustment every twenty years. Lessees are to have not more than forty acres of the surface of unentered lands for prospecting.

The Secretary of the Interior is authorized to grant prospecting permits for chlorides, sulphates, carbonates, borates or nitrates of potassium or sodium, or associated similar salts, for a period of not exceeding two years. Areas are likewise limited in this case to 2560 acres. Upon discovery of valuable deposits, permits are to be entitled to patents for 640 acres. Leases are to be permitted upon terms similar to those outlined in the case of phosphates or phosphate rock. In addition to the 640 acres, 20 acres are to be allowed for camp sites, refining works, etc.

The provisions of the act apply to deposits "owned by the United States, including those in national forests, the Grand Canyon National Monument, and the Mount Olympus National Monument," but excludes those in national parks, "and in lands withdrawn or reserved for military or naval purposes."

The provisions of the act as to coal specifically excludes deposits in Alaska. Common carriers are not allowed to take coal deposits larger than needed for their own purposes, and are limited to one lease for each 200 miles of line. A royalty and lease-fee system, such as is specified for phosphates and phosphate rock is provided for coal.

In the case of oil and gas, prospecting permits are provided for, upon lands "located within ten miles of any producing oil or gas well." In the territory of Alaska prospecting permits may be granted for periods not exceeding four years. Patents for leases may be granted for one-fourth of the land embraced in the prospecting permit. Timber is reserved to the United

States. Leases shall be for a period of twenty years, subject to renewal, the payment to be not less than \$1 per acre per annum. Rights-of-way through public lands for pipe lines are provided for.

The rights conferred by the act are upon "citizens of the United States, or to any association of such persons, or to any corporation organized under the laws of the United States, or of any State or territory thereof, and in the case of coal, oil, or gas, to municipalities." No corporation shall hold any interest as a stockholder of another corporation in more than one lease, No lessee shall hold more than a tenth interest in any agency engaged in the sale or resale of coal, phosphate, oil, gas, potassium or sodium, obtained from such lessee. Moneys derived are to be paid into and appropriated as a part of the Reclamation Fund.

Hearings on Proposed Dyestuff Tariff

Hearings were held on Jan. 14 to 15, before the House of Representatives Committee on Ways and Means, for the purpose of obtaining information on the dyestuff situation in order that legislation may be passed if possible to encourage the industry in the United States. The subject of the hearing was the so-called Hill bill (H. R. 702), which would place a duty on all dyes and intermediates. Technical experts, manufacturers of dyestuffs, and representatives of dyestuff consumers were present and testified at the hearing.

About the same time as the opening of the hearings, the Bureau of Foreign and Domestic Commerce issued a report by Thomas H. Norton (Special Agent Series No. 111). In this report Dr. Norton gives the status of the dyestuff situation as in November, 1915. He states that before the war 3300 tons of dyes were made here, while now about 15,000 tons are made. A list of the industries dependent on dyestuffs is given, together with a list of the present manufacturers of intermediate and finished dyes. Dr. Norton states that the Department of State has exerted every effort for eight months to secure the free passage of German dyestuffs to our ports. No results have thus far been obtained. The Department of Commerce has also exerted every effort to alleviate the situation and is strongly in favor of protecting and fostering the American industry. The manufacture of coal tar crudes, Dr. Norton says, has assumed large proportions, but, owing to the great demand for such products in the manufacture of explosives, the dyeworks cannot get adequate supplies.

At the hearings before the Committee on Ways and Means, which is the tariff-making body of the House, the general consensus of opinion was strongly in favor of the bill. As to its effect, the general opinion seemed to be that it would not give much immediate relief except in unloading whatever supplies might be hoarded, but its future effect would be to encourage present manufacturers to increase their output and to induce new capital to enter. Some were in favor of a dumping clause, in addition to the bill to prevent unfair competition after the war. The possibility of using the dye factories for explosives was also strongly brought out, and future chemical independence and the foundation of an American organic chemical industry were other strong points presented in favor of the bill.

The first expert called by Chairman CLAUDE KITCHEN was Dr. BERNHARD C. HESSE, representing the chemical and dyestuff committee of the New York Section of the American Chemical Society. Dr. Hesse first read a letter of the committee to Hon. E. J. Hill under date of Jan. 7, 1916. (The original report of this committee, which furnished the basis for the Hill bill, was published in our issue of December, 1914, Vol. XII, page 753.)

LETTER FROM CHEMICALS AND DYESTUFFS COMMITTEE

NEW YORK, January 7, 1916.

HON. E. J. HILL,

House Office Building, Washington, D. C.

SIR: H. R. 702 is, in part, based upon the report of the chemicals and dyestuffs committee to the New York section of the American Chemical Society appearing in the Congressional Record for December 10, 1914, copy of which is hereto attached.

The undersigned, constituting the complete membership of seven of that committee, herewith submit, at your request, their justification of—

(1) The rates proposed in that report and by you incorporated into H. R. 702, and

(2) Their expectation that as a result of such duties a complete, self-contained, and independent coal-tar chemical and dye industry will eventually result in the United States.

The professional activities of these seven men and the industrial occupations represented by them on this committee are as follows:

- (1) Manufacture of heavy chemicals.
- (2) American coal-tar dye producers.
- (3) Textile interests.
- (4) Importers of coal-tar dyes.
- (5) American producers of crude coal-tar products.
- (6) Leather and tanning interests.
- (7) Chemical expert in coal-tar dyes.

In 1882 this country possessed a coal-tar dye industry that promised to grow into something worth while. There was then a duty of 35 per cent ad valorem and 50 cents per pound specific. When this specific duty was removed in 1883, whatever we then had of a coal-tar dye industry languished and has since been practically without effect. A specific duty has since then not been levied.

In 1908 two of the largest American coal-tar dye plants then in existence (Schoellkopf, Hartford & Hanna Co., of Buffalo, and Heller & Merz Co., of Newark, N. J.) submitted to the Committee on Ways and Means under date of November 9, 1908, at the hearing of November 11, 1908 (pp. 128-130, vol. 1 of the official record of those hearings), a detailed statement as to the added protection they would require in order to compete successfully in this market against European-made dyes, but themselves using European-made intermediates. In that elaborate cost statement they showed that a proposed materials cost of 13.22 cents per pound for finished dyes as against an existing cost of 14.76 cents (i. e., a materials cost decrease of 1.54 cents per pound), together with an increase in the ad valorem rate from 30 per cent to 40 per cent, would enable them to successfully compete, although using foreign-made intermediates. At the same time and place they also showed that the corresponding materials cost for the same finished dyes per pound in Germany was 10.57 cents.

Reverting now to the tariff in effect in 1882, this committee is dependably informed that the then average import value of the great bulk—that is, from two thirds to three-fourths of all the European-made coal-tar dyes entering this country—was a little over \$1 per pound, and this notwithstanding the statement of from 50 cents to 60 cents made by Mr. John Campbell under date of July 26, 1882, at pages 154-156, volume 1, of the Report of the Tariff Commission of 1882. If this committee's information of the \$1 figure be correct, then the specific duty then in effect was essentially one-half of the fair average import value of the bulk of the dyes reaching this country from Europe.

This committee was further dependably informed that in 1914, before the outbreak of hostilities, the fair average import value of the bulk—that is, from two-thirds to three-fourths of all the dyes reaching this country from Europe—is 15 cents. If, therefore, the specific duty of 7½ cents be now added to the prevailing ad valorem of 30 per cent, the tariff conditions of 1882, under which we did have something in the way of coal-tar dye industry, would be substantially reproduced, and under those conditions it is not unreasonable to expect that the industry would again flourish in this country.

In all of the tariff legislation heretofore enacted some of the coal-tar dyes were put upon the free list; also the intermediates have been more or less (principally more) upon the free list. In other words, the protection afforded to the coal-tar dye industry has never been such as to cover the entire industry, but only segregated parts thereof. Each and all of these tariff enactments failed to provide for a co-ordinated protection of the making of intermediates and of the production of the finished dyes therefrom all in this country.

Therefore, this committee recommended that this isolated and "spotty" protection be removed and all dyestuffs, by

whatever name known and produced in whole or in part from materials obtained or obtainable from coal tar, should be treated alike for tariff purposes; all should be taxed 30 per cent ad valorem plus 7½ cents per pound specific.

In general, the German 1913 export price of intermediates is about one-half that of finished dyes. Therefore, this committee compensated the specific on finished dyes to the intermediates by adding a specific duty of 3.75 cents per pound on all intermediates. This committee suggested a 15 per cent ad valorem duty on intermediates as against 30 per cent ad valorem on finished dyes because, compared with the finished dyes, with the intermediates being made in larger units and larger amounts, the handling costs in manufacturing intermediates in the factory are less than the handling costs for finished dyes.

Returning now to the statement of Messrs. Schoellkopf and of Messrs. Heller & Merz above referred to, the added protection due to the three proposed increased ad valorem would amount to 1.5 cents on dyes of an average value of 15 cents entering this country. Adding this 1.5 cents to the 1.54 cents above shown gives, as a total, an added 3.04 cents protection per pound on dyes of the above-stated fair average import value.

As a test case of the net effect of this schedule of rates upon the production of the cheapest dyes, this committee further had the benefit of the following calculations based upon the assumptions now to be given:

The dye known as Orange II is probably the type of the cheapest of the dyes that are imported into this country. It is made by assembling two intermediates known, respectively, as sulfanilic acid and betanaphthol. In general, 173 pounds of sulfanilic acid and 144 pounds of betanaphthol will yield 350 pounds of the commercial dye in its highest commercial concentration. There were four cases assumed with regard to respective import values, as follows:

Case	Orange II	Sulfanilic Acid	Betanaphthol
	Cents	Cents	Cents
I	8	4	6
II	8	8	8
III	12	6	9
IV	12	4	6

The calculated respective added advantages for 6, 6.5, 7, 7.5, 8, 8.5, 9, 9.5, and 10 cents specific for the dyes, and half of each for intermediates with an ad valorem of 30 per cent and 15 per cent, respectively, in cents per pound of Orange II, due to this schedule of rates, would therefore be as follows:

Case	6 Cents	6.5 Cents	7 Cents	7.5 Cents	8 Cents	8.5 Cents	9 Cents	9.5 Cents	10 Cents
	Cents	Cents	Cents	Cents	Cents	Cents	Cents	Cents	Cents
I	2.61	2.88	3.16	3.43	3.70	3.98	4.25	4.52	4.80
II	2.34	2.61	2.89	3.16	3.43	3.71	3.98	4.25	4.53
III	2.13	2.40	2.68	2.95	3.22	3.50	3.77	4.04	4.32
IV	2.02	2.29	3.17	3.44	3.71	3.99	4.26	4.53	4.81

From this tabulation it is clear that 7.5 cents is the lowest specific rate that gives a practically 3 cents added protection per pound of this cheap dye under this variety of price circumstances and combinations.

It is therefore clear that the rates that this committee suggested meet the following three conditions:

(1) Recreate the tariff conditions of 1882 to conform as nearly as possible to the altered conditions of 1914.

(2) Give the industry that makes dyes from intermediates the added assistance that in 1908 it showed to be necessary for its continuance in business.

(3) Protect the domestic intermediates maker.

There is also the added advantage to the dye-making industry that all of the coal-tar dyes are dutiable and none are free and that all intermediates are dutiable and none are free.

That the committee's assumption that 15 cents represents the fair average import value of the bulk of the dyes reaching this country in 1914 is reasonably near the truth is shown further by the average materials and labor costs given in the statement of Messrs. Schoellkopf, Hartford & Hanna Co., and of Messrs. Heller & Merz of 1908 just referred to. The combined labor and materials costs in Germany of the 3,000,000 pounds of dyes there referred to is 12.62 cents per pound. Our present consumption of dyes is between 50,000,000 and 60,000,000 pounds per year.

In order to visualize the effect of these proposed rates

upon intermediates and dyestuffs and the total protection afforded, the following table is submitted:

PROTECTION AFFORDED UNDER PROPOSED RATES							
Cents per Pound	Specific	Ad Valorem	Total Protection	Cents per Pound	Specific	Ad Valorem	Total Protection
INTERMEDIATE DYES				FINISHED DYES—			
	Cents	Cents	Per ct.		Cents	Cents	Per ct.
4.....	3.75	0.60	4.35	109	cont'd		
5.....	3.75	0.75	4.50	90	7.5	3.0	10.5
6.....	3.75	0.90	4.65	76	11	3.3	10.3
7.....	3.75	1.05	4.80	69	12	3.6	11.1
8.....	3.75	1.20	4.95	62	13	3.9	11.4
9.....	3.75	1.35	5.10	57	14	4.2	11.7
10.....	3.75	1.50	5.25	53	15	4.5	12.0
11.....	3.75	1.65	5.40	49	16	4.8	12.3
12.....	3.75	1.80	5.55	46	17	5.1	12.6
13.....	3.75	1.95	5.70	44	18	5.4	12.9
14.....	3.75	2.10	5.85	42	19	5.7	13.2
15.....	3.75	2.25	6.00	40	20	6.0	13.5
16.....	3.75	2.40	6.15	38	21	6.3	13.8
17.....	3.75	2.55	6.30	37	22	6.6	14.1
18.....	3.75	2.70	6.45	36	23	6.9	14.4
19.....	3.75	2.85	6.60	35	24	7.2	14.7
20.....	3.75	3.00	6.75	34	25	7.5	15.0
25.....	3.75	3.75	7.50	30	50	15.0	22.5
FINISHED DYES							
8.....	7.5	2.4	9.9	124	75	22.5	45
9.....	7.5	2.7	10.2	113	100	30.0	37.5
					150	45.0	52.5

In 1913 the average export value out of Germany of intermediates was 10.07 cents per pound and of finished dyes 21.53 cents per pound. Therefore, these proposed rates give a total protection of 53 per cent to this average value of intermediates and of 65 per cent to this average value of finished dyes, and, furthermore, conform very closely to the tariff conditions in 1882 and satisfy the 1908 requirements of the United States dye makers mentioned; and, in addition, protect the entire class of coal-tar dyes and their respective intermediates and give the prospective American intermediate maker a protection which he has hitherto never enjoyed.

This committee further believes that with this protection on the cheaper dyes the domestic manufacture of the more expensive varieties of dyes, of pharmaceuticals, of medicines, and of explosives will follow almost as a matter of course.

In order that there may be given as little opportunity as possible for evasion of the duties contemplated to be imposed by the report of this committee, this committee now respectfully suggests to you that H. R. 702 further contain a definition of what is to be a coal-tar dye for the purposes of this act, so that such things which under our present adjudications are not coal-tar dyes and are not coal-tar dye intermediates will be obliged to pay the duty of coal-tar dyes.

The materials we have in mind are the dye bases known as magenta base, Victoria blue base, Victoria green base, Bismarck brown base, auramine base, crystal violet base, methyl violet base, rhodamine base, chrysoidine base, and the like, which are imported in that condition and merely require the addition of a small amount of muriatic acid thereto to convert them into the commercial forms of dyes. In the form of bases, they are neither dyes nor intermediates and they pay 20 per cent as coal-tar preparations; they are not dealt in on the European markets; they have no fixed market value; the importation value into the United States can be whatever the exporter chooses. In this connection it will be necessary to look into the language employed by the court in the decision reported under Treasury decision 34,400 in volume 26 for January to June, 1914, and 5 Customs Court of Appeals. Furthermore, the language used in the cases cited in Treasury decision 28,003 with regard to bromofluorescent acid should be consulted so as to prevent evasion along the line of those products which are dye acids and need merely the addition of a small amount of soda ash to convert them into commercial dye forms. It would not do to place these rates upon coal-tar dyes and then enable foreigners to ship into this country things that are not dyes and not intermediates under our present adjudications and which merely need the addition of a negligible amount of muriatic or other acid or of soda ash or of similar material to convert them into the real dyes of our adjudications. It is obvious that if any such loophole were permitted to stand the result expected of those rates would not take place—i. e., a complete, self-contained and independent coal-tar, chemical, and dye industry within the borders of the United States.

This committee further suggests that in placing natural indigo on the free list, the wording selected be such as possibly to exclude indigo not derived from vegetable sources from that free list.

From the point of view that the protective duty contemplated to be added by these proposed rates will reappear in whole or in part in the form of a direct addition to the normal cost of dyestuffs, it is clear that those users of dyestuffs that have in whole or in part hitherto enjoyed the free list will bear the greater relative proportion of such putative increase. Whether such addition will actually take place or not this committee expresses no opinion; it merely states the maximum that can reasonably be expected in the way of increased cost to the users of dyes in this country. In other words, as we stated in our above report, namely: It will, therefore, be necessary to determine carefully if the advantages to be gained are equal to the price to be paid.

The committee herewith unanimously reaffirms its belief that the rates proposed in its report of November, 1914, above referred to, are the lowest at which a self-contained, complete, and independent coal-tar, chemical, and dye industry can be created in this country, and which at the same time offer a legitimate incentive to legitimate capital for a legitimate effort to produce these goods in this country. Whether capital will avail itself of this advantage or not this committee expresses no opinion.

As to this schedule of rates proposed—

(1) It is the probable lowest schedule that will induce complete, self-contained, and independent manufacture within the United States.

(2) It meets and very closely duplicates the tariff conditions existing in 1882 when we did have something of an industry of this kind.

(3) It meets the requirements set forth in 1908 as necessary to maintain a dye industry in this country, which dye industry then operated with foreign-made intermediates.

(4) It provides at the same time a suitable protection to the making of intermediates within the United States.

(5) It puts all dyes of coal-tar origin upon one and the same level for tariff purposes and also puts all such intermediates upon one and the same level for tariff purposes.

(6) It gives a protection of 53 per cent on the average value of all intermediates and of 65 per cent on the average value of all finished dyes, such average values being average export values out of Germany for 1913.

Respectfully submitted.

BERNHARD C. HESSE, *Chairman*, J. B. F. HERRESHOFF, I. F. STONE, J. MERRITT MATTHEWS, H. A. METZ, D. W. JAYNE, ALLEN ROGERS.

Dr. Hesse said in the hearings on Jan. 14 that the rates proposed reproduce as near as possible the relative conditions existing in 1882, when this country did have something of an industry. They reproduce also, as nearly as possible, the added protection asked for in 1908, and a complete protection for manufacture of intermediates has been added. Furthermore, it is proposed to remove from the free list all products of this kind; in other words, protection is put on everything. In that way, by giving added protection to the manufacturer of intermediates in this country, and at the same time giving the manufacturer of dyestuffs, who employs these intermediates, the protection that he asked for in 1908, and reproducing at the same time the conditions of 1882, when this country did have something of an industry, are the reasons why it is expected—and believed that the expectation is justified—that if those conditions are reproduced in 1915 or thereabouts that this country will then have something of an industry.

Dr. Hesse said there were plenty of coal-tar crudes available before the war. He said it had been understood that Schoellkopf, Hartford, and Hanna of Buffalo had not been very successful since 1882. He said that when intermediates come in free this country only has an assembling industry, and when these are shut off the industry is choked. In regard to natural indigo being placed on the free list, Dr. Hesse said 95 per cent of the indigo used was synthetic, so this made little difference. He did not think the German industry was protected to any great extent by patents, as 99 out of 100 patents are "misfires."

Dr. Hesse said the dye users should co-operate with the manufacturers by telling them what they want and in what amounts. He said the difference in the cost of labor was one factor in determining a tariff.

Another factor discussed was the relation between explosives and dye manufactures. Dr. Hesse said: "We are rapidly approaching a position where we are independent of any foreign country except Chile for any materials that we may want for defense." If we had a complete coal-tar dye industry we would have an equipment and workmen which could quickly be shifted to making explosives. However, the two industries are not inextricably joined, as one could easily exist without the other. At present Dr. Hesse said our production of coal-tar products was going mostly for explosives. The output is greater than we would need for dyes. He said substantial relief could not be expected in from six months to three years.

A statement was read to the committee from the Monsanto Chemical Works, St. Louis, Mo., in which they stated that they had previously imported raw materials for their products, which are fine and medicinal chemicals. They have expended \$200,000 on new equipment to manufacture their own raw materials and want protection. They state that they will be supplying their products at reasonable prices in from thirty to sixty days.

Dr. J. MERRITT MATTHEWS, consulting engineer, of New York City, was next called. Dr. Matthews is a member of the committee of the American Chemical Society, of which Dr. Hesse is chairman, and said that he had come into pretty intimate contact with quite a number of textile organizations, and they have all evinced a strong desire to see a dyestuff industry established in this country, looking toward it as a method of insurance that present conditions shall not recur. He always understood production costs in Europe were far less than ours, but he could not state exact comparative costs. It is not a question of increasing costs to the textile men; it is a question of saying whether they shall continue in business. One per cent is a high average limit for cost of dye in the finished product. The addition in the price of goods is high now on account of abnormal price of dyes, but in normal times the increased cost with the proposed tariff on would be very small. One cent would cover the increase on a suit of overalls.

To make finished dyes requires an organization, and there is considerable inertia to overcome. People are loth to go into it unless they have assurance of protection. The bill would not prohibit imports, as there would be a demand for many dyestuffs not developed in this country. We should receive a practical benefit in twelve months, and some dyes could be made in three months. Others would take years.

Ability to make explosives is also an important point, and should be the first consideration. Great Britain has subsidized her industry with Government participation, under the name of British Dyes, Ltd. They have passed prohibitive laws dealing with Germany. Russia has done the same. Of course, resentment may have played a part in their action.

Dyes should be lower in price after a time through competition. It is not likely at present that the textile industries would ask for an increased tariff on textiles if a dyestuff tariff would be enacted. The levying of the tax would not produce the results it would have produced in 1908, when so many mills opposed the increase tariff on dyes. It is absolutely essential that intermediates be given protection to have a complete industry, and since the value of the intermediates is, roughly speaking, one-half the value of the dyestuffs, the committee concluded that the intermediates should bear one-half the ad valorem duty and one-half the specific duty of the finished dyestuffs.

Mr. L. A. AULT of Ault & Wiborg Co., Cincinnati,

Ohio, manufacturers of printing inks, said they were now making their own intermediates and some dyes for their own use, otherwise their factory would have been closed during the past four months on many essential colors. He was strongly in favor of the bill, and cited as an example the tin plate industry, which was fostered by the McKinley bill, while tin plate is now selling at much lower price than when the law was enacted, and this country is an exporter in the bargain. All colored printing stops when the dyes are shut off. Newspaper inks are, however, not affected.

Mr. HERMAN A. METZ, importer, manufacturer and consumer of dyes and also a member of Dr. Hesse's committee, said in part: The increased cost of dyes if made here would not affect consumers. Labor is not such an important item. The plant with which he is connected in Germany is running with two-thirds of its force. The 30 per cent duty covers the difference in labor costs. His company, the Consolidated Color & Chemical Co. of Newark, has expanded to three times its former size, and he is now making his own intermediates. The rates proposed are the minimum which are necessary. Benzol and acids at present are hard to obtain, due to munition manufacture. The bill will not help during the war as raw material cannot be obtained fast enough. This country will not make all colors, as the very fine colors will still be imported.

Mr. HERBERT H. DOW of the Dow Chemical Co., Midland, Mich., said that his company went ahead and took the chance, and is now erecting a plant with a capacity of 1000 lb. of dry indigo per day. He expects to have it finished in July. He is not confident of competing with the Germans until the tricks of the trade are learned. He thinks the tariff could be removed after the industry is established if dumping is prevented.

Prof. CHARLES H. HERTY, president of the American Chemical Society, said in part that he does not consider this question that is before us now as the usual tariff problem, but the mills of this country are suffering and a crisis is here. The organic industries are lacking greatly in this country in the way of chemical industries. It is impossible to develop all lines at once, so that the by-products of one industry could be used in another, as Germany has succeeded in doing in fifty years of experience. Apparatus is hard to get in view of the present shortage of steel, and methods given in the literature are often purposely deceiving.

Five or six years ought to be enough to get the majority of the manufacturers in good shape. As a Democrat he wrestled with this question a long time, and is now convinced that if this country is to have an industry it must have a protective tariff. He thinks one thing which has been shown up through the European war, and which is clear now to all, is the value of chemistry to a nation. His hope and desire to see the dyestuff industry proper is because it is going to stimulate all kinds of chemical work; it is going to put chemistry on a higher plane in this nation. It is to the interest of the cotton-goods men who look forward to export trade to have American-made dyes rather than get them from competitors in the cotton-goods business. There are a great many things brewing in this country ready to get started, and everyone is looking to Congress. There need not be unfair prices as a result of this tariff as German competition and the Sherman anti-trust law ought to prevent that.

Mr. J. F. SCHOELLKOPF, president of Schoellkopf Aniline & Chemical Works, Buffalo, N. Y., said in part: The rates proposed may be sufficient as the manufacturer of intermediates may be able to sell his products without being obliged to take full advantage of the proposed duty, but if a rapid expansion is desired the

rates should be increased. In addition to an adequate tariff on all coal-tar products and colors, some effective anti-dumping legislation will have to be enacted. Without such a clause, nothing can prevent the crushing of the domestic industry if the foreign conventions so decrees. Another question to be considered is whether or not the Government should assume some sort of supervision.

His company is making nearly all its own intermediates and the labor cost is about 40 per cent. They could make explosives in a week and go back to colors in a week. Only the intermediate plants are used in making explosives. They have increased their capacity 125 per cent since the war. He does not think anything like 15,000 tons of colors are now being produced. About 5000 tons is nearer the right amount. They have had experiences with unfair competition in the way of underselling. Dyes have been sold here for 18 cents, paying 30 per cent duty, when they were selling in Germany for 22 cents. His company expects to be making 7000 tons per year within the next two months, and could soon double that output if machinery could be obtained. The plant is already built for increasing to 7000 tons per year. They did it because they were enabled to make products from their raw materials and products for which their intermediates could be used. They tried to make enough to pay for the plant and make a profit besides. With increased production they ought to be in a better position to compete.

Mr. Schoellkopf submitted tables which he had previously submitted in 1908 and 1913, showing the cost of a complete plant and production costs for an output of 3,000,000 lb. of dyes per year. The production cost was figured as 1.34 times the cost in Germany under the proposed tariff and 1.44 times under the present tariff.

Dr. WM. BECKERS, president of W. Beckers Aniline & Chemical Works (Inc.), Brooklyn, N. Y., said that this country may even lose the 15 per cent of business it had before the war if the tariff is not revised. Alizarin dyes which come in free, constitute one-third of the money value of the entire importation. It is not fair to leave them untaxed. They are mostly the finer colors used on expensive material bought by well-to-do people who can better stand the increased cost than those using goods made with cheaper dyes. American consumers have not enjoyed the benefit of the duty-free colors as the foreign conventions have placed their prices as they wished. Revision must be done in a thorough and correct way so that alongside of the other already highly developed industries of the United States a "modern organic chemical industry" can be substantially and intelligently built up as a whole on American soil. The German Government will assist the dye-makers in preventing any foreign industry to develop. The rates proposed could be increased, but they may be sufficient. They surely will not create a hot-house industry. If the bill is passed he will have four or five millions at his disposal instead of one-quarter of a million.

Mr. EDWARD MOIR, president of the Carded Woolen Association, said that the increased cost on a suit of clothes would only be two-thirds of a cent.

Mr. H. B. THOMPSON of the United States Finishing Co., New York City, said the dyeing cost in cotton goods is only 0.15 to 0.18 cent and the increase would be infinitesimal. An advance of 5 cents in the price of indigo would raise the cost of dyeing cotton goods $\frac{1}{4}$ cent on a 3-yard drill and 1-10 cent on 7-yard 64-square calico. Eighty per cent of the New England trade favor the bill. As to entering into contracts with dye-makers for dyestuffs to help foster the industry, that is not practical on account of the changing styles.

Much more testimony was given of the present shortage in clothing, the effect of the shortage of dyes reaching way back to the cotton planter and sheep raiser, and various figures of cost were given as to increases which would result in the cost of goods. For the most part the opinion was that the increased cost would be slight, and in most cases would be absorbed before it got to the consumer. Some were skeptical as to whether any immediate relief would result, but all favored the bill as beneficial for the future. Among those giving further testimony were the following: Mr. Ludwig Stein, chairman of dyestuffs committee of National Association of Clothiers; Mr. George W. Wilkie of R. H. Comey & Co., New York; Mr. J. K. Milliken, representing the National Association of Cotton Finishers; Mr. Frederick E. Kip, president Saltson Textile Manufacturing Co.; Mr. W. D. Livermore, chief chemist American Woolen Co.; Mr. John Alden of Pacific Mills; Mr. Chas. L. Auger, president National Silk Buying Co., Paterson, N. J.; Mr. Horace B. Cheney of Cheney Bros.; Mr. John W. Snowden, representing the Upholsterers of Philadelphia; Mr. D. F. Waters, president Master Dyers' Association; Mr. Jos. E. Ralph, director Bureau of Engraving and Printing. Many letters were presented by Congressmen from the various manufacturing districts favoring the bill. The hearings adjourned at 8 p. m. on Jan. 15.

Congress Likely to Create a Tariff Commission

President Wilson is understood to have reached a decision to ask Congress to create a tariff commission, and it is said in Washington that it is more than likely that he will outline his views on the subject at the coming convention of the Chamber of Commerce of the United States, when he will speak before that body, the night of Feb. 10.

Such a proposal is likely to receive the approval of Congress, it is said in Washington, as many members of both political parties are in favor of such a commission. A place was made on the Ways and Means Committee of the House, the tariff body of the House, for Representative Longworth, when he returned to Congress, and almost his first act was to introduce a bill providing for such a commission. It is understood he was encouraged to do so by Democratic members, Mr. Longworth being a Republican.

President Wilson until recently believed, it is understood, that the Federal Trade Commission has the powers of a Tariff Commission, but he is now said to have come to the conclusion that the powers of that body are entirely too limited to meet the demands of the business world for a real tariff commission. The President will propose, it is said, a broad-gaged commission, with full power to treat the tariff in a scientific manner, and he may recommend that the commission be bi-partisan. The President, in common with other economists, it is said in Washington, has given consideration to the situation which will follow the European war, and has been urged to take measures which will prevent the "dumping" of foreign goods on the United States market when the war ends.

The bill of Representative Longworth, which may become the basis for debate and action, provides for a commission of five members appointed by the President, and holding terms of two, three, four, five and six years respectively, the term of each to be designated by the President but their successors are to be appointed for six years each. Under this bill the President would designate the chairman. Any member could, after a

hearing, be removed by the President for inefficiency, neglect or malfeasance. Not more than three members could be of the same political party. Votes would be by quorum. The chairman would receive \$7,500 a year and the other members \$7,000 a year. Rather large powers, under the bill, are granted for secretarial and other help, the latter assistance being mentioned in this way: "Such other employees as it may find necessary to the performance of its duties." The office of the commission would be in Washington, but it would have authority as a body or by one or more of its members "to conduct investigations at any other place or places, either in the United States or foreign countries." Expenses are allowed both for the commission and its employees and witnesses. The duties of the commission are thus defined under this bill:

"To investigate the cost of production of all articles which by any act of Congress now in force or hereafter enacted are made the subject of tariff legislation, with special reference to the prices paid domestic and foreign labor and the prices paid for raw materials, whether domestic or imported, entering into manufactured articles, producers' prices and retail prices of commodities, whether domestic or imported, the condition of domestic and foreign markets affecting the American products, including detailed information with respect thereto, together with all other facts which may be necessary or convenient in fixing import duties or in aiding the President and other officers of the government in the administration of the custom laws and such commission shall also make investigation of any subject whenever directed by either House of Congress."

The commission would make reports either to the President or Congress as they might direct. Power to require the production of books and papers of manufacturers, etc., is given. The bill prohibits the making public of information which would be of value to business competitors.

Electrochemical Industries as Affected by the War

Program of New York Section Meeting of the American Electrochemical Society

The program of the meeting of the New York Section of the American Electrochemical Society, to be held at the Chemists' Club on Feb. 11, is particularly interesting and timely, as the subject will be "The Electrochemical Industries as Affected by the War." This will be a joint meeting with the New York sections of the American Chemical Society and the Society of Chemical Industry. The speakers will be:

Lawrence Addicks, on electrochemical war supplies.
W. S. Landis, on air saltpeter.
E. D. Ardery, on hydrogen for military purposes.
Albert H. Hooker, on new war products.
William M. Grosvenor, on metallic magnesium.
G. Ornstein, on liquid chlorine.
George W. Sargent, on electric steel.

The date for the annual spring meeting of the American Electrochemical Society is April 27, 28, 29, and the place is Washington, D. C.

Program of 112th Meeting of American Institute of Mining Engineers

Arrangements for the annual meeting of the American Institute of Mining Engineers to be held in New York City from Feb. 14 to 17 have been completed, and everything points to a very interesting and enjoyable meeting. Headquarters will be at the Engineering Societies Building, 29 West Thirty-ninth Street, New York City.

Monday night, Feb. 14, will be college night, Tuesday night the smoker, Wednesday night the annual banquet at the Hotel Astor, followed by dancing, and Thursday will be devoted to an all-day excursion.

The technical program contains papers of great interest in the various sections. The meetings of the different sections are as follows:

Monday, Feb. 14: 10 a. m., session on petroleum and gas; 2 p. m., session on coal and coke; 2 p. m., session on geology.

Tuesday, Feb. 15: 10 a. m., business meeting and technical session; 2 p. m., technical session.

Wednesday, Feb. 16: 10 a. m., session on iron and steel; 10 a. m., session on precious and base metals; 2 p. m., session on iron and steel.

Resolution of the American Institute of Mining Engineers on the Chihuahua Murder

The following resolution was passed at the meeting of the Board of Directors of the American Institute of Mining Engineers on Jan. 21, 1916:

Resolved, That this Board has learned with indignation and sorrow of the unprovoked and brutal murder of eighteen American citizens on Jan. 10, in the State of Chihuahua, Mexico, and laments especially the death of Messrs. C. R. Watson, C. A. Pringle, H. C. Hase and W. J. Wallace, who were members of the American Institute of Mining Engineers. As these men and their companions were engaged in the lawful prosecution of their work, we trust that nothing will be allowed to prevent or delay appropriate action by our Government concerning the outrage by which they lost their lives.

Resolved, That the sincere sympathy of this Board and of all the members of the Institute is extended to the families and friends of Messrs. C. R. Watson, C. A. Pringle, H. C. Hase and W. J. Wallace.

And be it further resolved, that a copy of this resolution be sent to the Secretary of State of the United States, be published in the Institute's Bulletin, in the press, and be sent to the families of the deceased members.

Annual Meeting of the American Paper and Pulp Association

The American Paper and Pulp Association will meet in annual convention at the Waldorf-Astoria Hotel on Wednesday and Thursday, Feb. 16 and 17, 1916.

The entire day on Thursday will be given over to the Technical Section, a special meeting being held in the forenoon and a general meeting in the afternoon. Committee reports will be presented at the forenoon session, the following subjects receiving consideration: Soda pulp and recovery processes, Martin L. Griffin, chairman; Sulphate pulp and kraft paper, Otto Kress, chairman; Mechanical pulp and improvements in grinding, D. L. Bellinger, chairman; Sulphite pulp and processes, Robert B. Wolf, chairman; Reports on methods of testing materials used in the manufacture of paper, H. P. Carruth, chairman.

At the afternoon session the typical apparatus used in the manufacture of pulp and paper will be exhibited and their operation demonstrated. Special forms of barkers for pulpwood will be shown in this way and new methods of drying paper will be shown. It is intended to open the afternoon session to all interested in the pulp and paper industry irrespective of membership, and a large attendance is expected.

Headquarters for the Technical Section will be established at the Waldorf-Astoria Hotel, in charge of Thomas J. Keenan, secretary. The officers of the Technical Section of the American Paper and Pulp Association and the standing committees are:

Executive Committee—Henry E. Fletcher, chairman, Fletcher Paper Company, Alpena, Mich.; W. G. MacNaughton, Nekeosa-Edwards Paper Company, Port Edwards, Wis.; Ernst Mahler, Kimberly-Clark Company, Neenah, Wis.; Charles F. Rhodes, Bureau of Tests, International Paper Company, Glens Falls, N. Y.; Henry F. Obermanns, Hammermill Paper Company, Erie, Pa.

Publication Committee—Charles F. Rhodes, Bureau of Tests, International Paper Company, Glens Falls, N. Y.; Henry F. Obermanns, Erie, Pa.; Thomas J. Keenan, New York.

Soda Pulp Committee—Martin L. Griffin, chairman, Oxford Paper Company, Rumford, Me.; Sidney D. Wells, Madison, Wis.; Edwin Sutermeister, Westbrook, Me.

Sulphate Pulp Committee—Otto Kress, chairman, Forest Products Laboratory, Madison, Wis.; Joseph E. Hedin, Wilmington, Del.; George S. Holmes, Orange, Texas.

Sulphite Pulp Committee—Robert B. Wolf, chairman, Burgess Sulphite Fibre Company, Berlin, N. H.; F. C. Clarke, Washington, D. C.; C. C. Heritage, Port Edwards, Wis.

Standard Methods of Testing Materials Used in the Manufacture of Paper Committee—H. P. Carruth, chairman, American Writing Paper Company, Holyoke, Mass.; Raymond C. Hatch, Holyoke, Mass.; Max Cline, Glens Falls, N. Y.

Groundwood Committee—D. L. Bellinger, chairman, Finch, Pruyn & Company, Glens Falls, N. Y. Associates not yet named.

The Western Metallurgical Field

The Extension of Flotation

Of all the work that has been done with the flotation process, we have heard the least about its application to ores of metallic copper. Such ores, of course, are limited in distribution, being practically confined to the northern peninsula of Michigan. Nevertheless the recovery of finely divided metal is quite as much of a problem there as the slime problem is anywhere, and it is reasonable to presume that flotation should offer some advantages over present methods. This subject has been under investigation by the metallurgical department of the Michigan College of Mines, testing ore from two new properties. Flotation is found to give a much better extraction than ordinary gravity methods, but up to the present the concentrates produced are not sufficiently high grade to be handled in the type of smelting equipment usually found in Michigan. If flotation is to be applied with any degree of success, means must be found for producing a better grade of concentrate, or smelting methods must be revised. Both these suggestions are feasible, but in all probability the most advisable thing to do would be to improve the concentrates to meet the smelting conditions, since the latter are peculiarly adapted to the product of Michigan copper mills.

Progress with flotation is being made in the Cripple Creek district, where several companies have been making investigations for some months past. The Portland has definitely decided on the Callow pneumatic process, and is operating some machines in the old Stratton's Independence mill, which it purchased some time ago. It is likely that the Portland people will put this mill on a custom basis and handle ores from different parts of the district, as the plant is favorably situated for such work. Another concern that has been making extensive tests is the Vindicator, and there is a possibility that a large mill may be built for the treatment of low and medium-grade mine and dump ore.

The successful application of flotation to Cripple Creek ores appears to have been no simple matter, and several failures have been reported by individuals called upon to make tests. Those who have pursued their experiments further, however, have apparently succeeded where others failed. One essential to success seems to be the use of an unusually large quantity of oil, up to 6 lb. per ton. Such a quantity would entail considerable expense were it not for the fact that very cheap oils seem to be adapted to this work. It is in-

teresting to speculate on the future of flotation in Cripple Creek, and its effect on cyanidation. Flotation plus smelting may prove more economical than cyanidation of low-grade ores; or the cyanidation of flotation concentrates may be developed to a point where, by reason of the cheapness of flotation and the comparatively small quantity of high-grade concentrate to be cyanided, a much larger tonnage of ore may be treated in the district. Of course, it is impossible to say at this time what the developments may be, but there is a possibility that they may affect the status of present practice in the district, as well as the former strategic position of the mills treating high-grade ore at Colorado City.

Unusual conditions are being encountered in applying flotation to different ores. In the case of a certain zinc ore it was impossible to apply the process satisfactorily until copper sulphate was added to the water. In another instance, tests on a zinc ore gave satisfactory results at the testing laboratory in the city, but when the process was tried at the mill in the mountains the results were negative. Examination of the mountain water proved it to be almost free from salts; and suspecting that this might be the source of trouble, the metallurgist added mineral salts of various kinds to the water and accomplished that the results of test work were duplicated at the mill. Incidents like these give food for thought in regard to the theories of flotation, and lend weight to the arguments in favor of an electrical theory.

Tests on a Washington Complex Low-Grade Silver Ore

The department of mining engineering of the State College of Washington, under the direction of Prof. F. A. Thomson, has been conducting a research on the metallurgy of certain complex low-grade silver ores of Okanogan, Wash.¹ Some of the ores in this district consist mainly of pyrite, sphalerite, galena and tetrahedrite in a gangue of bluish-white quartz. The analysis of one of the ores is as follows:

	Per Cent
Copper	1.55
Lead	3.70
Zinc	4.3
Iron	6.25
Antimony	3.3
Lime	1.05
Sulphur	6.80
Silica	72.01
Alumina	0.7
Silver, oz. per ton	26.0

Assays of the segregated minerals of the ore show the gold to be contained in the galena and tetrahedrite. Silver is more widely distributed, but is mainly concentrated in the tetrahedrite. The results are shown below:

Mineral	Gold, Oz. per Ton	Silver, Oz. per Ton
Quartz	None	None
Pyrite	0.02	26.4
Sphalerite	None	29.5
Galena	0.16	71.1
Tetrahedrite (gray copper)	0.12	347.6

This ore was tested both by leaching and concentration; cyanidation and hyposulphite treatment being given under the first method, and gravity concentration and flotation under the second.

Cyanidation.—Treatment of the raw ore proved impracticable, yielding only 50 per cent extraction, with excessive cyanide consumption. Little or no improvement was gained by preliminary treatment with caustic alkali and metallic aluminium, as practiced at Cobalt. Chloridizing roasting followed by cyanidation gave an extraction of 65 per cent, the loss being 15 per cent in roasting and 20 per cent in the tailing. Sulphatizing roasting followed by water wash to remove soluble cop-

¹Bulletin 101.

per proved entirely unsuitable as a preliminary treatment. The best result was obtained by a light, thirty-minute chloridizing roast, water wash and cyanidation. This gave a total extraction of 88 per cent, the loss being 7 per cent in roasting and 5 per cent in cyaniding. The extraction of copper by the water wash was above 80 per cent.

Hyposulphite Treatment.—Oxychloridizing roast followed by water wash and leaching with sodium hyposulphite gave a silver extraction of about 70 per cent. Copper extraction by water wash was about 80 per cent.

Concentration Tests.—Treatment of each screen size in glass sorting column yielded an extraction of 70 per cent; ratio 10:1. Cyanidation of the tailing recovered an additional 18 per cent, making a total recovery of 88 per cent by the combined treatment. Straight concentration on a Wilfley table, with ore crushed to 40-mesh, gave a recovery of 80 per cent; ratio 4:1. A combination treatment was given by tabling the —40 + 100 grade and floating the —100. The tabling gave a recovery of 80 per cent with a ratio of $4\frac{1}{2}$:1; and flotation with eucalyptus oil in acid solution gave an extraction of 73 per cent at a ratio of $3\frac{1}{2}$:1. Treatment by flotation exclusively gave the highest recovery, 91 per cent of the silver and 95 per cent of the copper. The ore was crushed to pass 80-mesh and was floated with a mixture of eucalyptus oil and wood creosote in non-acid solution. The concentration ratio was $2\frac{1}{2}$:1.

The tentative choice seems to lie between (a) light chloridizing roasting followed by water wash and cyanidation, and (b) flotation of the entire ore crushed to pass 80-mesh. The latter process, of course, yields a product which may have to be shipped to smelters, but experiments are under way to determine the feasibility of cyaniding this product after a light chloridizing roast followed by water wash.

Producing Tungstic Acid at Boulder, Col.

Until quite recently the only local treatment of Boulder County tungsten ores consisted in concentration, the enriched products being shipped East for metallurgical treatment. At different times various concerns have investigated the advisability of further local treatment, producing a finished product suitable for use in metallurgy, chemistry or the textile industry, but nothing came of these investigations. Within the past month, however, the Tungsten Products Co. has been incorporated by J. H. Holmes, H. B. Holmes and Warren F. Bleecker, for the manufacture of tungsten products at Boulder, Colo. Mr. Bleecker is metallurgist in charge of technical work.

The immediate purpose of the company is the production of tungstic acid. Later on metallic tungsten may be produced. The raw material is low-grade tungsten ore mined in the Nederland district immediately west of Boulder. Low-grade ore is being used in preference to high-grade concentrate on account of the much lower cost per unit of tungstic acid contained. In brief the process consists in roasting the ore with soda ash, leaching the sodium tungstate with hot water and precipitating tungstic acid with hydrochloric acid. The ore and soda ash in proper proportions are ground in a pebble mill. The mill is lined with maple wood and the grinders are flint pebbles of local origin. The ground mixture is roasted on a reverberatory hearth, observing important precautions to secure a high percentage of soluble sodium tungstate, as well as certain physical conditions in the product which will make the subsequent leaching efficient. The roasted mixture is then transferred to vats where it is leached with water heated by live steam. The solution is filtered by vacuum, and tungstic acid is precipitated

by the addition of hydrochloric acid. This precipitate is separated from the liquor by decantation and filtration, and forms a product of immediate commercial value. While the elements of the process are comparatively simple, the success of the work depends on maintaining certain conditions in each step. The work at Boulder is starting on a small scale, with plans for enlarging as conditions demand.

Sulphuric Acid in Utah

An index of the development of chemical and metallurgical industry in Utah is found in the announcement by C. W. Whitley, general manager for the Utah department of the American Smelting & Refining Company, that his concern will shortly erect in the Salt Lake valley a sulphuric acid plant. It is reported that the manufacture of acid will be in conjunction with the smelting operations of the company, utilizing the sulphurous smelter gases. If the company's experiments in zinc hydrometallurgy with electrolytic deposition prove successful enough to warrant the construction of a commercial plant, much of the sulphuric acid produced will be used in the treatment of zinc ores.

Anaconda's Electrolytic Zinc Plant

The success of Anaconda's experiments in the production of electrolytic zinc is definitely settled by the announcement that a \$2,000,000 plant is to be constructed at Great Falls where cheap electric power is available. Research on this subject has been under way for months, and will now culminate in a plant that is to be in operation about September of this year. The reported capacity is 70,000,000 lb. per annum, and the power requirement 30,000 hp. Zinc concentrate will be roasted and leached with sulphuric acid. The solution will then be purified by precipitating iron by means of limestone and copper and cadmium by zinc. The purified zinc sulphate solution will then be electrolyzed with insoluble lead anodes and either aluminium or zinc cathodes.

Potash Production in Utah

The Mineral Products Company, which is exploiting the alunite deposits near Marysvale, Utah, now has its plant in operation and is producing about 25 to 30 tons of potassium sulphate per day. This pioneer work, started under the favorable conditions created by the war, is meeting with success, and the company is now contemplating the production of aluminium as well as potash. A carload of alumina by-product from potash manufacture has been shipped East for experimental tests, with the expectation of ultimately building a reduction plant in Utah. The concern is backed by men prominent in the packing and mining industries.

Record Production in the Joplin District

Joplin is rejoicing in a production of lead and zinc in 1915 valued at over \$26,000,000. This is a record that has no equal in former years, the nearest approach being in 1912, when the value was over \$18,000,000. Zinc concentrates constituted the largest portion of the tonnage and commanded the highest price per ton of any product of the district. In June the base price for 60 per cent zinc concentrates reached the record price of \$135 per ton. The new year opened with prices of \$85 to \$115 per ton for 60 per cent zinc and \$70 for galena, and the prospect for continued prosperity is as bright as could be asked. There appears to be no cessation in the construction of new mills and treatment plants following in the wake of high prices, and new settlements have even sprung up around plants constructed by some of the larger companies.

The Utilization of Wood Waste

A paper read at the Baltimore meeting of the American Institute of Chemical Engineers, on Jan. 12, 1916.

BY ARTHUR D. LITTLE

Mark Twain says, "We all talk about the weather, but nothing is done." So it is with wood waste utilization. The lumbermen are interested, of course, but their interest is tempered by weariness and restrained by scepticism. They are open to conviction but would like to see anyone who can convince them. Much the same situation may be found where any of our great industrial wastes are concerned. Those who are responsible for the wastes are so close to them and so long familiar with them that they have come to regard them as the unavoidable accompaniment of the industry. Moreover plans for waste utilization commonly involve the extension of a business into regions which, however familiar they may be to those doing business in them, are new and strange to the makers of the waste. Conversely, those whose specialized experience might enable them to utilize the waste to advantage, hesitate to incur the large capital expenditure required for establishing an industry dependent upon a raw material over which they have no control and the supply of which may cease at any time, as, for example, when a lumber mill burns down.

These are real and serious obstacles in the way of the utilization of wastes, but the things which any one can do easily bring no great rewards. The world belongs to those who overcome difficulties and nowhere does it offer richer promise of potential wealth made actual than in the colossal wastes of lumbering.

The figures involved are of astronomical proportions and consequently make little more impression on the mind than the distances of the fixed stars. Let us, however, try once more to really comprehend them. On a total annual cut of 50,000,000,000 ft. broad measure, of merchantable lumber, at least 75,000,000,000 ft., or about 112,000,000 tons of wood waste is produced. For every man, woman and child in the country there is therefore annually wasted more than a ton of wood.

The proportion of waste to merchantable lumber varies within wide limits with the kind of wood. In the lumbering of hard woods, according to Goodman, only 15 per cent of the weight of the standing timber appears as finished lumber. Sixty-five to 70 per cent of the original tree is left on the ground and the mill waste amounts to over a cord per 1000 ft. of lumber. Frankforter, who had exceptional opportunities for studying the lumber industry in the middle, northern and western States reports that in these sections of the country the best equipped and most skillfully operated mills utilize a little less than 40 per cent of the total weight of wood in lumber, lath and shingles. Our own large scale studies on long-leaf yellow pine have proved that under the best operating conditions only 33.42 per cent of the average tree becomes available as lumber, box shooks, lath and shingles. Two-thirds is wasted. In the estimate given above of total annual waste an average of 60 per cent of the entire tree was reckoned as waste, but in view of the loss on yellow pine, which is our most important timber tree, and the far greater proportionate loss on hardwoods, it is evident that the total annual waste is substantially more than 75,000,000,000 ft. and may even reach 90,000,000,000 ft. Frankforter's estimate of 100,000,000,000 ft. on a smaller annual cut is undoubtedly too high and not in accordance with his other figures.

Of all our timber trees none lends itself more readily to waste utilization than long-leaf yellow pine. It is cut more largely than any other species and the individual operations are commonly on a great scale

which ensures the local concentration of waste in vast amounts. For these reasons and because my associates and I have studied the waste utilization problems presented by this wood more carefully than those of any other species I will ignore hardwood distillation, the use of extracted chestnut chips for pulp and paper making and the occasional use of mill waste from northern conifers in sulphite pulp mills, and ask you to direct your attention solely to the utilization of wood waste from long-leaf yellow pine.

The present annual cut of this species is about 15,000,000,000 ft., board measure. The waste is equivalent to 30,000,000,000 ft. It may be said at once without fear of successful contradiction that the potential profits in this waste are far greater than any actual profits which this branch of the lumber industry can be made to yield from lumber. When this waste is intelligently considered, not as waste, but as raw material, it will be seen to afford a basis for building up the greatest group of co-related by-product industries the world has ever seen. The products of these industries will comprise wood pulp, pulp boards, paper, paper bags, paper twine, turpentine, rosin, pine oil, charcoal, tar, ethyl alcohol, cattle feed, varnishes, ether, and not improbably acetic acid, wood alcohol, acetone and producer gas.

The wood of long-leaf pine is heavy, exceedingly hard, very strong, tough, coarse-grained, compact, durable and very resinous. Its density varies with the height from the ground, the age of the tree and its content of pitch or oleoresin. Sargent gives the average specific gravity as about 0.7, which would seem to be too high. Determinations in the Forest Products Laboratory ranged from 0.426 to 0.583. Determinations in our own laboratory gave 0.626 as the specific gravity of round wood averaging 7 in. in diameter. The weight per cubic foot for logging waste we found to be 39.1 lb. bone dry. The weight per cord depends greatly upon the shape and size of the pieces. On the dry basis we have found the sawdust to weigh about 1400 lb., mill waste with little or no bark 2340 lb., with much bark 1708 lb., logging waste in the form of fairly smooth round logs weighs about 3260 lb., and if rough and irregular will average 1860 lb., while mature long-leaf pine, consisting largely of heart wood, will run about 4300 lb. to the cord, bone dry.

We find the ultimate composition of long-leaf pine to be: Carbon, 53.96 per cent; hydrogen, 7.13 per cent; oxygen, 38.65 per cent; nitrogen, 0.03 per cent; sulphur, 0.04 per cent; ash, 0.16 per cent.

Our determinations of fuel value of average sawmill dust gave 9240 B.t.u., dry basis. Moisture in green wood averages 34.15 per cent, fresh green stumps average 28.69 per cent, lightweight 13.35 per cent. Stumps about six years old carry around 20 per cent of water and kiln-dried lumber contains an average of about 10 per cent.

The proportion of bark varies to some extent with the age of the tree and is relatively high. Small round Mississippi wood had about 9 per cent, Florida pulp wood over 11 per cent, and Florida trees, 18 in. diameter, bore 8.6 per cent of bark by weight.

Determinations in our laboratory of the fiber length of long-leaf pine gave a maximum of 7.40 mm., minimum 3.00 mm., with an average of 4.60 mm., as compared with 3 to 3.5 mm. for spruce.

In determining the amount of field waste under careful operation members of our organization selected five plots of one acre each as truly representative as possible of the average quality of yellow pine timber. As soon as the timber had been felled the waste between 3 in. and 9 in. was collected, classified and weighed. Much of it was also corded and scaled to determine relations

between weight, cord measure and volume. Each stump was measured and its volume and weight computed. Needles from four trees were weighed.

The main points of accumulation of mill waste are the main refuse conveyor and the main dust conveyor. Actual determinations by weight of the amounts of waste carried by these conveyors in very large scale operations were made by members of our staff. The results of these determinations in the field and at the mill enable us to state with a very close approximation to the truth the relative proportions of the initial products of the average yellow pine tree. They have perhaps never been ascertained before within such limits of accuracy or upon so large a scale. The proportions of the several products are as follows:

Tops and culls.....	22.35
Logs.....	70.56
Stumps and lightwood.....	7.09
	100.00

Bearing in mind that all percentages given are on the total weight of the tree, the tops and culls consist of:

	Per Cent
Needles and twigs.....	2.35
Limbs under 3 in.....	2.54
Cordwood.....	6.42
Pulpwood.....	4.54
Red and rotten.....	6.60

The logs yield:

	Per Cent
Red and rotten.....	1.45
Slabs, edgings and trimmings.....	18.07
Sawdust and shavings.....	17.62
Shingles.....	0.06
Lath.....	1.39
Lumber and box shooks.....	31.97
Stumps amount to.....	6.54
And lightwood to.....	0.61
	100.00

Comprehensive studies were conducted on these wastes for a period of eight months. The different classes of waste were carefully and repeatedly analyzed and their content of rosin and turpentine determined. Papers in great variety were made in our experimental paper mill under direction of Mr. V. E. Nunez, and extractions and distillations on the small commercial scale carried out in our Forest Products Department by Dr. L. F. Hawley. The results obtained, together with data from actual commercial practice, point incontestably to these stupendous totals:

Upon an annual cut of 15,000,000 ft. of yellow pine the lumber industry in our Southern states now wastes raw material sufficient for the concurrent daily production of 40,000 tons of paper, 3000 tons of rosin, 300,000 gal. of turpentine and 600,000 gal. of ethyl alcohol, together with fuel sufficient to meet the requirements of all these industries.

Despite the prevailing opinion to the contrary among lumbermen, and even among papermakers, long-leaf yellow pine lends itself admirably to the manufacture of paper. It is too pitchy for the sulphite process, but is readily reduced to pulp by the soda process. Much the best results are, however, obtained by the sulphate process which when carried out under proper conditions yields an excellent kraft pulp and paper. The pulp bleaches with some difficulty, but may with care be brought to good color without serious impairment of strength. The bleached pulp makes good wood writings and when mixed with pulp from gumwood can be run off into good book papers. A cord and a half of round waste makes a ton of paper as against about two cords of spruce costing Northern mills from \$9 to \$13 a cord.

The production of ethyl alcohol from yellow pine waste by the Ewen & Tomlinson process has been fully demonstrated as a technical proposition, about 90,000 gal. of high-grade 95 per cent alcohol having been made

in the plant of the Standard Alcohol Company at Fullerton, La. The commercial merit of the proposition remains to be demonstrated since this company is now in the hands of the receiver for reasons altogether apart from the technical merit of the process. It may, however, be said that every technical man familiar with the process believes that it is capable of producing 95 per cent alcohol at a cost, including cooperage and all fixed and manufacturing charges, of not more than 20 cents a gallon. Such alcohol is worth to-day about 56 cents a gallon. The yield per cord of sawdust or hogged wood waste containing 50 per cent water is 10 gal. in large-scale operation, but yields much higher have been obtained in the laboratory.

The process is based, of course, on the observation of Braconnot in 1819 that cellulose by treatment with mineral acid is converted into reducing and fermentable sugars. For nearly 100 years experimenters have endeavored to develop this observation into a commercial process. With the exception of Ewen & Tomlinson all have failed to produce alcohol in commercial quantities. Simonsen in Sweden, in 1889, began a series of brilliant researches which cleared up many points of difficulty and ultimately enabled him to secure very satisfactory results on the large laboratory scale. Attempts at commercial operation, however, developed fresh obstacles, and led to the abandonment of the process. The well-known German chemist, Alexander Classen, patented during the years 1900, 1902 and 1903 various modifications of the general process of producing sugars and alcohol by treatment of comminuted wood with strong acids under heat. Subsequently several plants were built in this country for carrying out one or another of these modifications. In none of them were any substantial amounts of alcohol produced and the Classen process must be regarded as commercially inoperative. It remained for Ewen & Tomlinson to overcome the fundamental technical difficulties underlying all these attempts and to put forward the first process capable of large-scale production of ethyl alcohol from wood.

The Ewen & Tomlinson process is essentially one for producing fermentable sugars. The fermentation of these sugars, once produced, may be carried out and the alcohol recovered in any distillery by the usual methods. It is my belief that the process affords the cheapest known method for producing these sugars, and that it therefore is ultimately destined to become an important if not the most important source of industrial alcohol.

In carrying out the process hogged wood waste usually containing about 50 per cent of water is loaded into a rotary digester holding about seven cords and having a protective and heat insulating lining. Sulphuric acid in relatively small amount is sprayed upon the wood and then steam is admitted to the digester. The critical temperature is reached as quickly as possible, and the reaction is then extremely rapid, if not indeed nearly instantaneous. Pains are therefore taken to immediately reduce the pressure and to empty the digester of its contents as promptly as may be. About 25 per cent of the weight of the wood is converted to reducing sugars, not all of which are fermentable.

The cooked material, which is not unlike coarse coffee grounds in appearance, is transferred by conveyors to a diffusion battery or other extraction apparatus in which the sugars are dissolved out. The spent chips go to a continuous press for removal of excess water and are then available as fuel. The extracted juice is neutralized with lime, and is then ready for fermentation. The concentrated slop from the stills finds use as cattle feed, and is about equivalent to molasses for that purpose.

In a modification patented by me the process may be

diverted as a whole to the production of carbohydrate cattle feed. In this modification hydrochloric acid is substituted for sulphuric and subsequently removed so far as readily possible by heating or blowing air through the mass. The remaining acid is then converted to common salt by addition of an equivalent amount of sodium carbonate. The juice is extracted and concentrated to the consistency of molasses.

A major economic problem in the South which is bound up with the utilization of wood waste is that of the agricultural development of the cut-over lands. It has been demonstrated that by a steam puller yellow pine stumps may be pulled for about 33 cents each. In the trials made the stumps averaged 563 lb. each, which makes the cost of pulling \$1.16 per ton. Where logging train roads are still in place the stumps can be brought to a central plant for treatment at a total cost well within \$2.50 per cord. Treated by solvent extraction they should yield per cord about 6 gal. of turpentine, 2½ gal. of pine oil and 380 lb. of resin. The extracted chips as pointed out by Veitch and Merrill, and amply demonstrated in our experimental paper mill, are available for the manufacture of an excellent grade of kraft paper. Strangely enough and contrary to our first impression the charred portions common in such stumps are easily removed in the process and leave the paper clean. The chips are, of course, also available for alcohol production.

Stumps and the highly resinous wood residues termed lightwood, together with the box slabs from turpentinized trees, are directly available for treatment by several processes of distillation. The average green wood, with 35 per cent moisture, contains about 6 per cent resin, but in selected samples of wood the resin may run higher than 50 per cent. No large quantities are usually to be had, however, containing more than 30 per cent. The composition of the resin itself is variable, but in green wood it runs about 80 per cent resin, and 20 per cent volatile oils; about 80 per cent of the latter are turpentine and the balance pine oil.

Destructive distillation is carried on in retorts operated commonly without temperature control. Average yields under these conditions are:

Light oils	6 gallons
Turpentine	6 "
Heavy oil	16 "
Tar	48 "
Charcoal	35 bushels

Various processes in which the retort temperature is controlled, as in the bath process and the processes of Gautier, Pritchard, and others, have been proposed, and several put in operation for a time on either the commercial or large experimental scale. They offer advantages in the way of better yields and quality of turpentine, but these gains are so nearly offset by higher fuel costs and higher maintenance charges that the commercial superiority of these more complicated processes has yet to be demonstrated.

Ten years ago recovery of turpentine from comminuted waste by steam distillation was practiced in many plants, the steam being blown through the mass of chips either upward or downward, and carrying with it to the condenser the volatile oils. The decline in the price of turpentine in 1907 and 1908 proved so severe a blow to the industry that it is to-day practically wiped out.

The well-known Yaryan process added to the steam distillation method the subsequent step of extracting the chips with a volatile solvent from which the dissolved resin could later be recovered. Several plants of large capacity were operated successfully until in 1913 the failure of the American Naval Stores Co. caused a heavy drop in the price of resin, which was

followed by the failure of the company operating the Yaryan process. A contributory cause may well have been the large losses of solvent incident to the process.

Several methods have been proposed for the recovery of turpentine, pine oil and resin from yellow pine wastes by the action of water solutions of alkali, but none are thought to be operating commercially. They depend upon the fact that the wood is only slightly attacked by the dilute alkali in which the resin is readily soluble. Nevertheless, some wood is dissolved, and the difficulty of separating this so-called "humus" from the resin has prevented the introduction of processes of this type. The difficulty has been overcome in a simple and ingenious way by Whitaker and Bates, who salt out the resin soap by increasing, after the initial treatment of the wood, the concentration of the alkaline solution to 3½ per cent free alkali. The treated chips are then available as a raw material for paper making.

When the real work of wood waste utilization has once begun and the attention of chemical engineers and financial men has been drawn more generally to the huge potential values now ignorantly thrown away we may expect the rapid development of these byproduct industries and the initiation of many new ones to the great enrichment of the South and in somewhat less degree that of the Northwest. It would doubtless be too sanguine to expect the directive impulse for this new development to come from the lumbermen themselves. They are too close to the wastes. They are blinded by the sawdust. But if they fail much longer to grasp the opportunity which has been so long beside them they must be content to see others reap the benefits and profits which will come through control of processes, special apparatus, and, above all, of technique.

Oils and Other Reagents in Flotation

BY ROBERT J. ANDERSON

The advent and application of the flotation process, as it is now understood by its more authoritative exponents, marks one of the most noteworthy and revolutionary advances in modern metallurgical endeavor. Flotation marks a new era in the concentration of ores and of intermediary mill products. Although the process was discovered some fifty-five years ago, it is only recently that mill men and others have come to a realization of its virtues and have applied its principles on a commercial scale. This tardy application of a process so long known must necessarily be ascribed to certain inherent difficulties, which were encountered and which could only be effaced by time. Since it is not so long ago that the process was uncertain of success, the rapid strides made in the last few years can be regarded as nothing short of remarkable. Recently flotation has demanded the attention of mine operators, mill men, and others interested in the mining and metallurgical welfare of the country, particularly the United States Bureau of Mines and the bureaus of experimental research in connection with the universities teaching mining and allied subjects.

Disregarding here the mention of the manifold number of patents which have been taken out for the flotation process, the subject of litigation, and the theories which have been advanced to explain the "why" of flotation, it may be safely stated that probably nothing relative to the application of flotation on a commercial scale has received the attention which the oils have. It is a well-known fact that virtually any kind of oil, grease, or oleic acid may be used in this process; the number of oils or rather combinations of oils which have

been tried experimentally and commercially is almost without end.

This use of oils has given impetus to the production of wood creosotes and other wood fractions particularly in the South, the market for which had hitherto become rather stagnant; further, the increased production of coal tars and similar distillates in coke and gas manufacture has lately been more warranted; then, too, the petroleum industry has had a share in furnishing oils for flotation consumption.

To-day there are probably 200 flotation plants in active operation in this country, and this number is rapidly increasing as time proceeds. The flotation process will undoubtedly have a far-reaching application, but in no sense can it be looked upon as a universal panacea for all metallurgical ills. There can be little doubt that the process has come to stay, and probably its full significance is not even now realized. The metallurgical treatment of the concentrates produced in flotation presents an entirely new problem not hitherto encountered in metallurgical work and also a field for active research.

Oils in Flotation

There are so many oils available for use in flotation work that judicious selection has become a factor almost as important as the quality of an individual kind. In spite of the fact that considerable experimental work has been performed pertinent to the use and application of oils in flotation, there is a decided dearth of data regarding their effects and action. It is known, however, that certain oils, or rather combinations of oils, are applicable to the treatment of certain ores while others are only remotely so.

These oils, generally in mixtures of one sort or another, have been employed as flotation oils; namely, coal tar and fractions from the distillation of coal, such as coal creosotes; castor oil (mixed in small amount with kerosene or burning oil); eucalyptus oil; pine oil; pine tar; pine-tar oil; rosin and rosin oil (used for the residic acid there in); wood creosote and other products obtained in the destructive distillation of wood, such as pyroligneous acid; petroleum products of different kinds when mixed with a small proportion of the wood oils or some of the coal-tar products.

Although certain oils have all the inherent properties which would suggest their applicability as flotation oils, the fact they are prohibitively costly must act as a strong deterrent either for their use or investigation.

In the United States the oils derived from the pitch pine have given the most satisfactory results on a commercial scale; whereas in Australia, which country is in the van in flotation to-day, the essential oil of eucalyptus has been the most successful. Recent commercial practice has shown that oils of mineral origin promote the best recovery in the case of copper ores, and that oils of vegetable origin, such as the pine oils, turpentine, wood tars, and creosotes are conducive to the best recovery in the case of galena and zinciferous material.

Broadly stated, flotation oils may be classed as "frothing" oils and "collecting" oils. There is at times some difficulty in grasping the distinction between frothers and collectors as such, for one oil in itself may, and often does, possess both frothing and collecting properties. The action of a frothing oil is such as to produce froth in greater or less amount, dependent on the frothing power of the oil. A collecting oil has a collecting power for sulphides in preponderance over its frothing action, being therefore, so to speak, a poor frother; a collecting oil may have simply a collecting action and little or no frothing action. As stated in

the foregoing, some oils combine both the properties of frothing and collecting in variable degrees of each. In the flotation parlance then, the classification is given: (1) Frothing oils; (2) collecting oils.

FROTHING OILS

The most successful frothing oils include the pine oils, cresylic acid, and turpentine and other pyroligneous products from the distillation of wood—notably methyl alcohol. The coal tar phenols and their near derivatives, and almost or all of the so-called essential oils are good frothers. The essential oil of eucalyptus finds favor, particularly in Australian practice, on account of relatively low cost and immediate supply. Castor oil, to which reference has already been made, when mixed 1:4 with kerosene has found application. The more volatile products of petroleum, including kerosene and gasoline, have been successful frothing oils.

On some ores crude pine tar combines the properties both of frothing and collecting; on other ores it is necessary to enrich the pine tar with some such oil as turpentine, pine oil, or wood creosote. Unquestionably, pine oil (steam refined or crude) is the best frothing agent known; however, generally the selective action is not positive and marked, and the concentrates will contain gangue in considerable amount. Experiments in this laboratory indicate that cresylic acid is particularly adapted to the flotation of zinciferous material, exhibiting both good frothing and selective properties.

COLLECTING OILS

So-called mineral oils and tar oils do not generally form a good flotation froth, but have a marked selective action on the sulphide minerals. Among the mineral oils are included the following: asphaltum base, crude petroleum, refined oil, gasoline, burning oil, creosol and coal tar and coal-tar creosotes. Oils derived from the destructive distillation of wood, such as wood creosotes, pyroligneous acid, and the like, are found to give the best recovery on galena and zinciferous material; coal-tar products are better adapted to the successful flotation of copper bearing minerals.

It is found that thick oils tend to form viscous, coherent flotation concentrates, while thin oils form less coherent masses. The action of coal tar in stiffening a weak, ephemeral froth is indicative of the former. In general the essential oils give a coherent froth and satisfactory extraction; oils like oleic acid or candle-maker's red oil, petroleum, and lubricating and engine oils have a strong tendency to produce heavy, thick granules which will not float. Oleic acid has a well-marked power to float silica.

Other Reagents in Flotation

The chemicals used in connection with oil flotation include the following: sulphuric acid, bichromates, permanganates, alkaline chlorides, alkaline sulphates and bisulphates, cupric sulphate, ferric sulphate, aluminium sulphate, thiosulphates and sulphites, organic electrolytes, such as tartrates, citrates, and citric acid, and others almost ad infinitum. Generally the purpose of other reagents than oil is to aid and abet a preferential flotation between the sulphide minerals or in some cases to effect a better separation of mixed sulphides from gangue material, unless indeed they be employed to counteract the deleterious action of certain soluble constituents in either the ore treated or in the water used, or both.

Recent commercial practice indicates that the use of sulphuric acid can be dispensed with if the proper oil combination can be found. Callow* very appropriately

*Bull. A. I. M. E., Dec., 1915, p. 2321.

remarks that the same results can be obtained in an alkaline or neutral pulp as in an acid one. Many mills have come to the use of almost no acid or even to an alkaline electrolyte; this latter promotes good recoveries in the treatment of pyrite as well as other minerals at times.

Experiments performed here on a 60-mesh product from the Joplin district containing pyrite and galena in a calcareous gangue show the following:

1. Potassium dichromate will deaden galena and permit the flotation of the pyrite—a true preferential flotation.

2. Alkaline sulphates, i.e., sodium and potassium sulphates, promote the production of clean concentrates; the same is true of ferric sulphate $\text{Fe}_2(\text{SO}_4)_3$.

3. Ferrous sulphate, FeSO_4 , and cupric sulphate were very harmful to the successful flotation of this particular product, flotation being practically impossible in their presence.

From these results and others of the same nature it is seen that it is of cardinal importance to ascertain the nature of the soluble constituents of the ore and also the nature of the water used in the flotation; proper precautions must be taken if anything of a deleterious character is present.

There seems to be considerable weight in the statement "a particular oil for a particular ore." In other words, no given oil can generally be employed effectively on a number of different ores. Further, different samples of the same oil will produce radically different results, as a small variation in homogeneity often engenders considerable difficulties. Usually acid will produce a concentrate free from silica, but its use can probably be just as well avoided.

Sizing.—Careful screen analysis with subsequent microscopic examination or wet analysis shows that in slimes, for instance, the bulk of the values obtain in the material that passes the finer meshings. And it is believed that the ordinary run of ores require grinding to 60-mesh at least for oil flotation treatment.

Microscopic Examination.—The microscope is an invaluable aid in flotation work of an experimental nature, effecting a large saving of time which would otherwise be consumed in tedious and long drawn-out quantitative analysis. Casual inspection under the microscope will give at once a pretty definite idea of the grade of the tailing, middling, or concentrate. Quantitative analysis is, of course, the final criterion on which to base results. The binocular microscope is more satisfactory than any other type.

Results of Experiments on a Settled Product from the Joplin District.—Additional experiments performed on the product mentioned above warrant these conclusions:

1. A satisfactory oil mixture would be: 5 parts wood creosote, 2 parts pine oil, 0.5 parts coal tar; or part of the pine oil may be replaced by soap solution in variable amount, thus reducing the cost.

2. A pulp dilution of 3.5:1 or 3:1 works well; the general run of data indicate that the pulp could be run as thick as possible within limits which would be occasioned by the fouling of the operation due to clogging of the test machine.

3. The action of the coal tar here is to stiffen the froth which for any reason might become weak.

4. The effect of temperature was practically nil.

5. Sulphuric acid does not increase the tenor of the concentrates.

Coal and Coke Efficiency in Blast Furnace Operation

BY BIRGER F. BURMAN

Coal Efficiency

The factors that principally influence the value of a certain kind of coal for the blast furnace are ash and sulphur. Phosphorus, of course, must not be present above certain small limits, but as there are no means by which any part of the same can be eliminated, it will not here be considered. The only thing left for the coal-mine superintendent to do is to watch for the limit, stipulated by the coke maker; if the phosphorus content should be too high, the coal must be used for some other purpose.

With the ash and sulphur it is different. There is some chance of diminishing the amount of these elements in the coal, thereby making it more suitable; and as both ash and sulphur are quite deleterious in the blast furnace, any fraction of 1 per cent of either, that can be kept out, means money saved in the operation. It is, therefore, important to be on a constant guard against such materials, and as the mine is the proper place for improvements, a system of efficiency should there be inaugurated. It will then be easier for the mine superintendent to furnish a product, that ought to command a higher price than before.

It is not the scope of this article to go into the subject of coal washing, etc., or any necessary means by which the ash and sulphur constants may be lowered. No such work of improvements, however, can be made without some kind of an indicator, whereby it can be judged and the interest of the men kept up. Such an indicator is the "efficiency" percentage.

For any comparison there must be a standard. In this case local conditions will govern the nature of the same and an analysis may be adopted which is a fairly true average at the coal heretofore mined. Extremes should be excluded and only reasonable analyses for maximum and minimum amounts of ash and sulphur be adopted. For instance, coal from a certain mine gave the following analyses (dry) during a year's time:

	Ash, per Cent	Sulphur, per Cent
Maximum . . .	12.00	1.35
Minimum . . .	8.00	0.75
Average . . .	10.00	1.05

This analysis may be adopted as a standard for next year's work and by assuming the minimum to represent 100 per cent efficiency, the "efficiency" of any other percentage composition may be figured out as in the following examples:

Example 1

A certain coal analyzed 10.37 per cent ash and 1.13 per cent sulphur.

To find its "efficiency" we have an increase in ash of $10.37 - 8 = 2.37$ per cent (over the minimum of the preceding year).

$$(2.37 \times 100) \div 8 = 29.625.$$

Hence $100 - 29.625 = 70.37$ per cent is the "efficiency" for ash.

The increase in sulphur percentage over the minimum of the preceding year is $1.13 - 0.75 = 0.38$.

$$(0.38 \times 100) \div 0.75 = 50.667.$$

Hence $100 - 50.667 = 49.33$ per cent is the "efficiency" for sulphur.

Example 2

A certain coal analyzed 7.92 per cent ash and 0.70 per cent sulphur. To find its "efficiency" we have a de-

crease in ash below the minimum of the preceding year of $8 - 7.92 = 0.08$ per cent.

$$(0.08 \times 100) \div 8 = 1.$$

Hence $100 + 1 = 101$ per cent is the "efficiency" for ash.

The decrease in sulphur is $0.75 - 0.70 = 0.05$.

$$(0.05 \times 100) \div 0.75 = 6.667.$$

Hence $100 + 6.667 = 106.67$ per cent is the "efficiency" for sulphur. With the shipment the following report is forwarded to the coke ovens:

COAL SHIPMENT NO.

P		per cent	
Efficiency: For ash		per cent	
For sulphur		per cent	
Total		per cent	

Coke Efficiency

The value of a certain coke for blast-furnace operations is dependent on its chemical analysis, and its physical structure. As for the moisture, this may be neglected as far as it concerns the operation of the blast furnace, especially, where the gases are washed; however, it should be recorded for the sake of giving an idea of how much water is unnecessarily handled and paid for; also for the sake of determining the weight of dry coke used.

Phosphorus is, of course, of great importance, but as there is such a slight chance, if any, to diminish it, it may be safely left out in any system of coke efficiency. However, it should be noted as a record and as a check on the coal mine.

While it would be desirable to have a constant composition of the ash, there is no way by which this can be accomplished. Therefore, to record the *detailed* analysis of the ash would be of no value.

The actual value of a coke is dependent on the amount of available fixed carbon it can furnish the blast furnace, consequently the coke should be high in fixed carbon and low in ash. But in order to reach a high grade of perfection in this respect, it will be necessary to pay strict attention to moisture and volatile matter.

The object of an efficiency system, as outlined below, should be not only to improve the quality of the coke but to keep it at the same uniform analysis and physical structure. Uniformity is just as important for the blast furnace as quality because expensive disturbances are caused by a variable quality of the stock and not by a uniform stock, even though poorer.

The efficiency system being merely an indicator will give no rules or methods of working in order to keep up or improve the quality of coke produced. It will be entirely up to the coke-oven superintendent to do this. As he will be in constant communication with the coal-mine superintendent, he can demand the proper kind of raw material; after that his attention must be directed on the ovens.

The following factors are more or less subject to improvements:

- Physical structure of the coke.
- Volatile matter on the decrease.
- Fixed carbon on the increase.
- Ash on the decrease.
- Sulphur on the decrease.

Regarding the physical structure it is entirely a matter of judgment and practical experience to properly define its nature and value. Certain prearranged rules in this respect must therefore be established.

As was said under coal efficiency, there must be a

standard of comparison. Such a standard may here be the average analysis of coke (dry) for a considerable length of time, say one year, with fair maximum and minimum values defined. As an example the following analyses may be given:

	Maximum, per Cent	Minimum, per Cent	Average, per Cent
Moisture	3.50	1.50	2.50
Volatile matter	2.00	1.20	1.60
Fixed carbon	86.40	84.30	85.35
Ash	13.80	12.50	13.00
Sulphur	1.05	0.75	0.90

This analysis may be used for the coming year and by giving 100 per cent efficiency to:

Fixed carbon for its maximum	86.40 per cent
Moisture for its minimum	1.50 per cent
Volatile matter for its minimum	1.20 per cent
Ash for its minimum	12.50 per cent
S for its minimum	0.75 per cent

the efficiency of any other analysis may be determined.

EXAMPLE

A certain coke gave the following analysis:

Moisture	2.59 per cent	
Volatile matter	1.90 per cent	
Fixed carbon	85.78 per cent	on dry coke
Ash	12.32 per cent	100.00 per cent
Sulphur	0.83 per cent	

To find its efficiency we proceed as follows:

Moisture:		
Increase: $2.59 - 1.50 = 1.09$		
$(100 \times 1.09) \div 1.50 = 72.67$		
Efficiency: $100 - 72.67 = \dots$		27.33 per cent
Volatile matter:		
Increase: $1.90 - 1.20 = 0.70$		
$(100 \times 0.70) \div 1.20 = 58.33$		
Efficiency: $100 - 58.33 = \dots$		41.67 per cent
Fixed carbon:		
Efficiency: $85.78 \times 100 \div 86.40 = \dots$		99.28 per cent
Ash:		
Increase: $12.32 - 12.50 = -0.12$		
$(100 \times 0.12) \div 12.50 = 0.96$		
Efficiency: $100 - 0.96 = \dots$		99.04 per cent
Sulphur:		
Increase: $0.83 - 0.75 = 0.08$		
$(100 \times 0.08) \div 0.75 = 10.67$		
Efficiency: $100 - 10.67 = \dots$		89.33 per cent

If the moisture, volatile matter, ash and sulphur should be of lower percentages than those given for the standards, the decrease in each case will, of course, add a corresponding percentage to the 100 per cent. For instance, if the ash content was 12.02 per cent. the decrease would be 0.18 and the efficiency $100 + 100 \times 0.18$

$\frac{12.20}{12.50} = 101.48$ per cent. The total analysis efficiency of the coke given in the example above may be considered to equal the sum of all the four efficiencies divided by 4. The total analysis efficiency is therefore $\frac{41.67 + 99.28 + 99.04 + 89.33}{4} = 82.32$ per cent. The

moisture efficiency is treated separately.

The physical structure may be given factors according to certain prearranged rules, each factor representing the efficiency given by the factor. It is not necessary to stipulate so many factors; only the factors 100-90-80-70-60-50 will do. These figures will then also stand up for 100-90-80-70-60-50 per cent efficiencies respectively.

Every coke shipment is sampled and analyzed. The following form for reporting the analysis may be used:

ANALYSIS OF . . . HOURS COKE			
From coke shipment No.	Coal shipment No.		
Number of cars:			
Weight in tons of 2000 lb:	tons		
Moisture		per cent	
Volatile matter		per cent	
Fixed carbon		per cent	
Ash		per cent	per cent on dry coke
S		per cent	per cent
P		per cent	per cent

(Moisture is driven off without determination and coke is analyzed "dry")

ON COKE SHIPMENT No.

	Wet	Dry
Moisture (average of the daily analyses)	2.50%	1.60%
Volatile matter Sulphur in combustibles not Fixed carbon } included.	82.32%	85.35%
Ash	12.53%	13.00% 99.95%
Phosphorus (remaining in the ash)	0.024%	0.025%
Sulphur (remaining in the ash)	0.130%	0.900%
Sulphur (remaining in the combustibles)	0.750%	
Total	100.014%	

Ash—12.684, figured on wet coke—analyzed:

[illegible]

Figures as shown have been put in only for exhibition. Sulphur is considered to be present as CaS, therefore CaO found should be adjusted accordingly.

$$P.O. = 2.29 \times P.$$

$$\text{CaS} = 2.25 \times \text{S}$$

$$\text{Ca in CaS converted into CaO} = 1.75 \times S.$$

In order to determine the fluctuations in value of coke, it is necessary to figure out the relative value of coke used. In this way it will be possible to determine fairly well the losses due to improper quality of the coke.

Standards will be necessary here as in anything else for making comparisons. Averages for some previous period, say one year, may be adopted; but the figures given below must be understood to be merely used for illustration purposes; they should be adjusted to suit local conditions.

Standards:

- | | |
|---|--------|
| 1. Cost of coke per ton of 2000 pounds, here assumed to be | \$2.20 |
| 2. Cost of limestone per ton of 2240 pounds, here assumed to be | 1 10 |
| 3. Cost of sand* per ton of 2240 pounds, here assumed to be | 1 10 |
| *This term stands for acids. | |
| 4. Cost of slag from tapping to its disposal by the railroad per ton of 2240 pounds, here assumed to be | 0 20 |
| 5. Amount of pure fixed carbon to melt the slag: = 0.22 pounds per pound of slag. | |
| 6. Ratio of acids to bases in the slag here assumed to be 1. | |
| 7. Analysis of limestone, see below. | |
| 8. The relative value of any coke shall be determined by the cost per ton of 2000 pounds of pure available fixed carbon to the furnace. | |
| 9. The relative value of coke, ash and slag from flux uncleaned into the furnace slag. | |

Example:

A certain coke (wet) gives the following analysis:

Moisture	2.50%	[SiO ₂]	6.02%
Volatile matter	1.56%	Al ₂ O ₃	3.61%
Fixed carbon	82.52%	CaO	0.666%
Ash	12.53%	MgO	0.24%
P (remaining in the ash)	0.024%	FeO	1.80%
S (remaining in the ash)	0.130%	P ₂ O ₅	0.053%
S (remaining in the combustibles)	0.750%	CaS	0.293%
		Total	12.684%

Going to the $sl_{3\sigma} = 12.684 - 0.055 = 12.629$

Standard analysis of limestone used:

SiO ₂	5.80 per cent	9.80 per cent acids
Al ₂ O ₃	4.00 per cent	
CaO	46.54 per cent	
MgO	2.78 per cent	50.21 per cent bases
Fe ₂ O ₃	0.89 per cent	
P ₂ O ₅	0.023 per cent	0.01 per cent
CaS	0.340 per cent	0.15 per cent
CO ₂	39.63 per cent	
Total	100.003 per cent	

REPORT NO. ON COKE CONSUMED AT BLAST FURNACE NO.

During the week ending ...

Date _____

[illegible]

Going to the slag: $9.80 + 50.21 + 0.34 = 60.35$

Limestone required to each 100 pounds of fuel burnt = y pounds

SiO ₂ . . .	6.02 + 0.0580y	Acids	= 9.63 + 0.0980y
Al ₂ O ₃ . . .	0.61 + 0.0400y		
CaO . . .	0.666 + 0.4654y		
MgO . . .	0.24 + 0.0278y	Bases	= 2.706 + 0.5021y
FeO . . .	1.80 + 0.0089y		
CaS . . .		CaS	= 0.293 + 0.0034y
		Total	12.629 + 0.6035y

$$9.63 + 0.0980y = 2.706 + 0.5021y$$

$$y = 17.13 \text{ pounds of limestone}$$

$$\text{Slag formed} = 12.629 + (17.13 \times 0.6035) =$$

$$\text{Sulphur present in coke.}$$

$$\text{in limestone } 0.1713 \times 0.15 =$$

$$\text{Sulphur in slag (per cent)} 90.57 \div 22.97 =$$

$$\text{Total per pound of fuel burnt:}$$

$$\text{The cost of slag } \$0.20 \times (1 + 1.12) \times 0.2297 \div 0.7728 =$$

$$\text{Cost per ton of 2000 pounds of pure available carbon.}$$

$$\text{Cost per ton of 2000 pounds of coke } 3.118 \div (1 + 0.7728) =$$

COST (SULPHUR CONSIDERED)

Only a limited amount of sulphur can be kept in solution by the blast furnace slag without danger of being absorbed by the pig iron. Often the amount of slag is quite sufficient to take care of the sulphur, brought in by the fuel, but more often extra slag has to be provided for. This is quite an item, as will be seen from the following.

A new standard has to be adopted, namely, the amount of sulphur the slag shall be allowed to carry. This will here be assumed to be 1.40 per cent for our special example.

22.97 pounds of slag satisfy $0.2297 \times 1.40 =$	0.3216 S
Sulphur present (see above) . . .	0.9057 S
Net sulphur for which outside slag must be provided	0.5841 S
(See Coke and Limestone, Supplement, Case V.)	
Requirements: Slag produced	46.70 pounds
Fixed carbon consumed 18.23 $\times 0.5841 =$	10.65 pounds
Stone consumed 19.36 $\times 0.5841 =$	46.35 pounds
Sand or its equivalent 32.07 $\times 0.5841 =$	18.73 pounds
Total per pound of fuel burnt:	
Fixed carbon	0.7728 - 0.1065 =
Limestone	0.1713 + 0.4635 =
Sand or its equivalent	0.1873 pounds
Slag	0.6967 pounds
Carbon efficiency of coke	66.63 per cent
Sulphur in coke	0.88
Sulphur in stone $0.6348 \times 0.15 =$	0.0952
	0.9752 S
Sulphur in slag (per cent)	97.52 $\div 69.67 =$
The cost of coke	\$2.30 $\times 1 =$
The cost of stone	1.10 $\times (1 + 1.12) \times 0.6348 \div 0.6663 =$
The cost of sand or its equivalent	1.10 $\times (1 + 1.12) \times 0.1873 \div 0.6663 =$
The cost of slag	0.20 $\times (1 + 1.12) \times 0.6967 \div 0.6663 =$
Cost per ton of 2000 pounds of pure available carbon	\$4.701
Cost per ton of 2000 pounds of coke $4.701 \div (1 + 0.6663) =$	3.132
Cost due to sulphur alone (no cost for reduction included) per ton of 2000 pounds	
of coke $3.132 - 2.410 =$	0.722

The report on coke consumed as shown at the bottom of page 139 is filled out every day and at the end of the week completed on the average analysis.

AVERAGE ANALYSIS FOR THE WEEK:

	Dry	Wet	
Moisture			SiO ₂
Volatile matter			Al ₂ O ₃
Fixed carbon			CaO
Ash			MgO
P. remaining in the ash		Total ash	FeO
S. (remaining in the ash)		Total S	P ₂ O ₅
S. remaining in the combustibles			CaS
Total			
Slag produced per unit of coke burnt			
Sulphur in slag		per cent	Sulphur not considered
Carbon efficiency			
Cost per ton of pure available carbon			
Cost per ton of coke			
Cost per ton of coke due to sulphur alone			

(To be concluded)

An Electrically Heated Bomb Furnace

BY D. F. CALHANE AND H. A. LAVENE

Certain classes of chemical reactions are carried on under pressure in sealed glass tubes. The most common of these reactions are those for the determination of chlorine, bromine, and iodine in organic substances by heating them under pressure with nitric acid.

The type of furnace most generally used consists of from eight to ten iron pipes that are fastened in a frame, enclosed by an air bath that is heated by gas ring burners. Channels around the pipes for air circulation provide for even heating. To protect against injury from the explosions of the tubes that frequently occur, there is a swinging triangular door at the ends. The rate of heating is determined by the size of the gas flame.

This furnace has several disadvantages, such as the following: With gas heating it is more or less difficult to bring the furnace up slowly and evenly to full heat and then maintain a constant temperature for a considerable interval of time. Varying gas pressure and air drafts seriously interfere with even heating. The explosion door does not work to full satisfaction. It allows of drafts; and particles of glass from the explosion of tubes in the top pipes, are reflected back into the lower tubes, causing these to explode. Glass particles from exploding tubes in lower pipes are sent out into the room from the fact that the door swings too far out from the impact with the longer lever arm. The gas flames are invariably put out by an explosion, causing delay.

For these reasons, the electrically heated furnace described in this article was designed and constructed. This does away with all gas troubles, and the new type of door devised eliminates dangers from flying glass particles.

In the construction of the furnace, eight small iron pipes are arranged around the central larger pipe, in a circle. These eight pipes are of $\frac{3}{4}$ -in. standard wrought-iron tubing, and the central pipe is $1\frac{1}{2}$ -in. tubing. The pipes are 25 in. long. A pin is inserted near the end of the pipes and a corresponding slot is cut in the retaining frame, thus permitting the removal of the tubes from the furnace for unsealing the contained glass tube.

The heating element is nichrome wire of the ribbon type. This is wound on insulated iron pipes that form the outer and inner winding frames. The outer pipe is a 25-in. section of 6-in. steam pipe, and the inner pipe is a 23-in. length of the standard $1\frac{1}{2}$ -in. wrought-iron tubing. For insulating the heating wire from the iron pipes, a $\frac{1}{8}$ -in. layer of alundum cement is used. The mass of iron gives good inertia to sudden possible heating variation, and thus makes for even temperature rise. The windings on the outer and inner frames are in series, giving the simplest electrical arrangement. The inner winding frame is easily removable through a detachable plate in the retaining frame. The wire on the inner frame is wound over the alundum-cement covering and then covered with a thin outer layer of the same cement. Over all is a jacket of thin sheet iron to protect the winding from mechanical injury.

In the case of the outer winding, the wire is wound with $\frac{1}{2}$ -in. space between the convolutions and covered with a thin layer of cement to protect from oxidation. A removable heat insulating muffle of alundum cement composition comes next, and around this a jacket of magnesia pipe insulation, such as is commonly used for steam-pipe covering. The air film between the two jackets will be a more efficient heat insulator than a solid joint. The desirable thickness of these insulating jackets was given from those used in another furnace

Improvements to Smelter.—Improvements to cost \$100,000 will be made to the Tacoma smelter of the American Smelting & Refining Co.

of same type, designed and operated here for various heating purposes. The general appearance of the heating elements is shown in Fig. 1.

In devising an explosion door an attempt was made to avoid the troubles that arise with the use of the hinged, triangular type of ballistic door.

When a reaction tube explodes in the furnace, the gas pressure sends the glass fragments out and smashes them against the end door. So the door has to relieve the gas pressure and withstand the blow of the glass fragments. The usual type of door is hung on the furnace at an angle of 30 deg., with the idea that the force of the explosion will carry the door out to 45 deg., where the law of incidence and reflection angles will cause the glass fragments to be entirely deflected down to the supporting bench on which the furnace stands. The failure of the door to act properly is due to two reasons. One is that the force of the blow varies, and secondly that the lever arm is shorter in case of an explosion from the upper tubes than it is where an explosion from the lower tubes occurs. These surmises were tested experimentally as follows: A rifle loaded with scatter shot was fired through the different tubes against the swinging door. Beforehand the other seven tubes, the wall behind the door, and the top of the table beneath, were covered with sheets of paper. The different paths of the shot could thus be registered on the paper. There were eight tubes in the furnace, two in a row, and four rows high.

In the case of the two middle tubes, the door worked fairly well. No particles of shot were deflected back into the other pipes and none were projected out into the room. In the case of the two lower tubes, nearly all the shot went out into the room. When fired from the top tubes it was found that nearly all the shot was deflected into the next tubes lower down. The effect of this in exploding other tubes heating in the lower rows is easily imagined. These experiments showed very conclusively that the swinging, ballistic type of door is unsatisfactory. After some study, a pop valve type of door was designed. This would consist of an iron cap, $\frac{1}{4}$ in. thick, and 11 in. in diameter, with a $\frac{1}{8}$ -in. flange $1\frac{1}{4}$ in. deep on the rim. This cap fits over each end of the furnace and supports the door mechanism. The door frame consists of an iron, flat ring, 3 16 in. thick and $8\frac{3}{4}$ in. in diameter that is hinged to the cap. Secured to this door ring are two cross strips of $\frac{1}{4}$ -in. x $\frac{3}{8}$ -in. stock, whose ends are bent down to form feet that are screwed to the ring. In this way, $\frac{3}{4}$ -in. clear-

FIG. 1—HEATING ELEMENTS

FIG. 2—DRAWING OF DOOR AND FURNACE END

ance between the under side of the cross strips and the door proper is attained.

The door itself is an iron disk 6 in. in diameter and 5 16 in. thick. Four screws secured to the cross strips pass four holes in this disk with a $\frac{1}{16}$ -in. clearance. Four conical springs on the shank of these screws, exert tension on the disk, which has a 30-60-deg. bevel around it, forming a shoulder that allows the disk to find its own set against the inner edge of the flat ring, and thus make a tight closure under the spring tension. At whatever point the disk is struck, it will give and release the pressure against the spring tension, returning instantly to its fixed position. The whole mechanism is fastened to the end caps by a catch arrangement.

The furnace is supported on feet, at a height of 6 in. from the table, and rests in two semicircular iron hoops secured to the supporting frame work. The furnace is tilted by making two of the feet $\frac{3}{4}$ in. shorter than the others.

A face and sectional drawing of the door and furnace ends is given in Fig. 2; also a view of the completed furnace in Fig. 3.

The next problem was to calculate the input sufficient to reach a maximum desired temperature at a desired rate. The upper temperature limit was set at 350 deg. C. that is to be attained in four and one-half hours. The rate of heating for the kind of work the furnace is to do must be even and fairly slow, and under good control.

Until very recently there was no path open to a satis-

FIG. 3—COMPLETE FURNACE

factory solution of such a problem, and cut and try was the only course. After a study of the papers by C. Hering¹ and I. Langmuir² a set of principles was selected from them that appeared to lead to a satisfactory approximation of the results desired. These principles deduced in these papers, although concerned with the design of large furnaces, might be also applied to small ones.

1. In a rather approximate calculation of this sort the heat losses by conduction only will be considered. In a furnace of this type, radiation and convection losses will be very small.

2. The wattage input is always balanced at equilibrium by the heat loss through the walls.

3. The flow of heat through a furnace wall is almost exactly analogous to the flow of electricity. The different components of the wall offer resistance to the flow of heat just as certain media do to the flow of the electric current. The total resistance of different layers is the sum of their separate resistances if in series. So the electrical formula $R = r + r' + r''$ applies, in which R is total resistance and r, r', r'' the separate resistances.

The volt or pressure factor is comparable to the temperature. The ohm is similar to the thermal resistance unit or "thermal ohm." The ampere is likened to the amount of heat flowing. The analogy breaks in that the temperature coefficient of the thermal ohm has a negative sign.

4. The thermal ohm is that unit of resistance requiring a drop of 1 deg. C. for 1 watt of heat flow.

5. From the above the ordinary resistance formula may be applied:

$$R \text{ (resistance)} = \frac{L \text{ (depth of wall)} \times r \text{ (spec. resistivity)}}{S \text{ (average cross-section)}}$$

6. Carrying out the analogy of heat and electricity still further, Ohm's law may be applied to represent the flow of heat.

$$T \text{ (temp. drop between inner and outer surfaces)}$$

$$W \text{ (heat flow in watts)} = \frac{T}{R \text{ (thermal resistance in thermal ohms)}}$$

7. From (5) and (6) we get by substitution

$$W = (TS)/(lr)$$

8. According to Nusselt, the thermal resistance is halved for every 273 deg. rise in temperature. Therefore the higher the temperature, the lower the resistance, and the greater the heat loss.

9. A joint or a crack makes a very good heat insulator. Still air is a poor heat conductor. A porous substance is a good heat insulator as it contains a large amount of still air. The effect of contact resistance is met with when heat flows from one medium to another.

10. Waste space in a furnace should be avoided. The smaller the insulating air space the better.

11. The average cross-section of a wall will be figured as the arithmetical average of the surface of the inner and outer walls, or

$$\frac{1}{2} [S \text{ (area outer surface)} + S \text{ (area inner surface)}]$$

The dimensions of the furnace are as follows:

Length of outside winding frame.....	= 25 in.
Inside diameter of outside winding frame.....	= 6.125 in.
Outside diameter of outside winding frame.....	= 6.625 in.
Outside diameter of alundum insulation.....	= 7.125 in.
Outside diameter of muffle insulation.....	= 8.875 in.
Outside diameter of magnesia covering.....	= 11.000 in.
Length of inner winding frame.....	= 23 in.
Diameter of inner winding frame.....	= 2.25 in.

From the foregoing principles and dimensions the thermal drop through the walls was determined.

The constants for the thermal resistances of the materials in the furnace insulation were corrected to represent the average resistance between 25-350 deg. C. Most of the constants were given in Hering's tables, *op. cit.*, between limits 20 deg.-188 deg. C. We have as the corrected resistivities between 25 deg.-350 deg. C.

Iron.....	0.8
Magnesia covering.....	500.0
Asbestos cement.....	120.0
Still air.....	100.0
Alundum cement.....	15.0

A typical calculation of the heat loss from the outer winding through the insulating walls will suffice to show the general method of approximating this value. The heat flow is from wires to asbestos muffle, to magnesia covering out to outside air. Asbestos muffle:

Average surface = $\frac{1}{2}(S + s)$, in which S and s are the areas of outer and inner surfaces respectively.

$$1. \text{ We have then average area} = \frac{\pi DL + \pi dl}{2} =$$

$$3.1416 \times 7.125 \times 25 + 3.1416 \times 8.875 \times 25 = 630 \text{ sq. in.}$$

$$2. R = \frac{\text{depth} \times \text{sp. resist.}}{\text{av. cross-section}} = \text{resistance of wall to flow of heat.}$$

$$\frac{0.875(\text{depth}) \times 120 \text{ sp. resist.}}{630 \text{ av. cross-section}} = 0.167 \text{ thermal ohm.}$$

Solving again by (1) for magnesia covering we have 781 sq. in. for average cross-section. Applying this value in (2) equation we obtain 0.678 of a thermal ohm.

The total resistance to heat flow of outer covering will be R for asbestos plus R for magnesia, or $0.678 + 0.167 = 0.845$ thermal ohm, the total resistance. Applying from principle (6) the formula:

$$W = \frac{T}{R}, \text{ or loss in watts, } W \text{ equals total temperature drop, } T \text{ divided by thermal resistance}$$

$$\frac{350^\circ \text{ (inside temperature)} - 50^\circ \text{ (outside temperature)}}{0.845 \text{ (total resistance of insulation)}} = \frac{300}{0.845} = 355 \text{ watts.}$$

Similarly, the loss from inner winding was calculated to be 205 watts. The total thermal resistance from inner winding out was, air space, 0.642; thin alundum and sheet iron on inner winding tube plus iron of outer 6-in. pipe, plus $\frac{1}{4}$ -in. alundum on outer pipe, 0.005 thermal ohm. As above, outer coverings, 0.845 thermal ohms. Total, 1.492 thermal ohms. 300 over 1.492 = 205 watts.

Loss from both ends through media of iron frame or pipe, plus air space, plus iron door, was 150 watts.

Total loss of heat from furnace was then

Heat loss from outer element.....	355 watts
Heat loss from inner element.....	205 watts
Heat loss from ends.....	150 watts

710 watts at 350 deg.

Next, it is desirable to know the number of watts that expended in the furnace will raise its temperature 1 deg. C. This gives the heat equivalent of the furnace. There are 80 lb. of iron in the construction and 10 lb. of alundum. The specific heat of iron from 25 deg.-350 deg. is 0.135; the specific heat of alundum is likewise 0.198. The iron equivalent is $80 \times 454 \text{ (mass in grams)} \times 0.135 = 4903$ calories. The heat equivalent for alundum is $10 \times 454 \times 0.198 = 899$ calories. This gives a total of $4903 + 899$, or 5802 calories.

The time it will take the furnace to rise to a given temperature will be determined by the energy supplied per second, energy lost per second, and the heat equivalent of the furnace.

The heat equivalent has been figured above, and the energy lost per second at certain temperatures has been

¹Carl Hering, Heat Insulation of Furnace Walls. 1910-1912 Met. & Chem. Engineering.

²Langmuir, Melick & Adams. Flow of Heat Through Furnace Walls. 1913. Trans. Am. Elec. So. Vol. 24, p. 53.

calculated. The supply of energy is to be determined. At 350 deg. temperature for the inside of the furnace the loss has been calculated to be 710 watts through the walls. Then the approximate time to rise to 350 deg. C. would be figured as follows:

$$\begin{aligned} \text{Time in hours} &= \frac{350 \times 5802 \times 4.2 \text{ (cal. to watts)}}{3600 \times (\text{input} - \text{aver. loss}) \text{ per sec.}} \\ &= 4.3 \text{ hours.} \end{aligned}$$

If we figure on an input of 900 watts and a loss of 710 watts at 350 deg., the average loss from room temperature up to 350 deg. will be 355 watts. This gives 4.3 hours, as approximate time of heating with 900 watts. From this it will be seen that 900 watts is a desirable input, that allowing for temperature coefficients in windings will raise the furnace to 350 deg. in about four and one-half hours. This was found to be the case in actual test as shown later.

In winding the furnace, allowing $\frac{1}{2}$ in. between convolutions, and with 24 in. winding surface on outer element, the calculation gave 98 ft. for outer and 20 ft. for inner tube. The ratio of masses of outer to inner is as 5 to 1. Total length of wire 118 ft. It was calculated that 120 ft. of $\frac{1}{8}$ -in. ribbon should allow 900 amp. to flow without undue heating of the wire. Accordingly, No. 18 nichrome ribbon wire was chosen from the Driver-Harris specifications. This gave a ribbon nearly $\frac{3}{64}$ in. thick and $\frac{1}{8}$ in. wide.

In winding this wire on the inner tube, which is $2\frac{1}{4}$ in. in diameter gross—that is, including the aluminum insulation—it was first wound in a lathe on a $1\frac{1}{2}$ -in. arbor under sufficient tension to hold the turns in place. The lathe gears were set for a 2-in. thread that gave two turns per inch with $\frac{1}{2}$ in. between turns. On releasing the tension a spring was obtained of exactly $2\frac{1}{4}$ in. diameter. This was slipped over the inner heating element, and twisted until the turns laid tight. A coating of aluminum cement was applied, and over this was wrapped a double layer of thin asbestos paper. The whole element was now covered with a sheath of thin iron to protect the winding from possible injury in withdrawing the heating tubes.

In winding the wire on the outer cylinder, this had to be done by putting the pipe into the lathe and winding on the wire, securing the ends by clamps. Care must be taken not to use too much tension as the aluminum insulation is apt to be cracked off.

In the testing of the completed furnace, a series of four constantin-thermo couples were used, each one being placed in a pipe differently situated in the furnace. These couples could be rapidly read by a master switching arrangement, with a mirror galvanometer,

whose scale was calibrated against the vapor temperatures of different chemical substances.

With an average of 106 volts and 8.2 amp. the furnace reached 350 deg. in four and one-half hours. With an average of 8 amp. and 108 volts the final equilibrium temperature was 450 deg., attained in eleven and one-half hours.

Fig. 4 below gives a heating curve that is averaged from four different heats. This is accurate within 10 per cent.

The explosion doors were tested by heating tubes thinly sealed and carrying as much as 6 c.c. of nitric acid until they exploded. The doors worked very well. Only a fine dust of glass came into the room that was carried out by the acid fumes. To avoid all possible chance of this, sheet iron hoods are slipped over the ends of the furnace. These are 5 in. deep and have a hole in the center $3\frac{1}{2}$ in. in diameter, covered with wire gauze for release of air pressure during explosion. These hoods prevent any glass whatsoever coming into the room, and also muffle the sound of the explosion to a dull rumble, whereas it is ordinarily like a heavy rifle report.

This furnace, with hoods as just described, can be attached to any suitable commercial 110-volt circuit on any bench in the laboratory without causing any trouble to near-by workers.

For regulating the temperature through certain desired intervals, a rheostat was devised with a dial switch, as shown in the cut of the completed furnace. This provides for ten steps in the temperature scale, from 200 to 450 deg. in intervals of 25 deg.

From calculations previously given, it is found that at 200 deg. the wattage supplied to the furnace is 260. At this point the maximum resistance needed is in series with the furnace.

The calculation of this resistance may be performed as follows:

Let E be the supply voltage — 110; also let I denote the value of the current flowing. Wattage desired 260. The resistance of the furnace is $R = 13$ ohms. Desired resistance in the rheostat R' . Then $E = I(R + R')$, or $110 = I(13 + R')$. Also power or wattage $= EI = 260 = RI$. Whence $260 = I \times 13$ and $I = 4.15$ amp. Substituting in equation above — $110 = 4.15 \times (13 + R')$; whence $R' = 13.5$ ohms.

So a length of wire having a total resistance of 13.5 ohms is desired.

Now at 350 deg. heat in the furnace, the wattage input is $710 = EI = RI$, whence $710 = I \times 13$, and $I = 7.4$ amp. Substituting, we have $E = I \times (R + R')$; when $R' = 1.37$ ohms in resistance box. Then the potential fall through resistance box equals from the proportionality law — $E : E' :: (13 + 1.37) : 1.37$; when E' , the drop in resistance box, equals 11.6 volts. The wattage consumed is $11.6 \times 7.4 = 86$ watts. Similarly for lower limit of 200 deg. The current flowing is 4.15 amp. and resistance in box is 13.5 ohms. The potential drop figures 56 volts, and the wattage is $4.15 \times 56 = 232$ watts. This gives maximum heating wire must stand. On the basis of these figures, No. 17 nichrome wire was selected, having 264 ohms per 1000 ft. The box is constructed of sheet iron built on slate slabs; it measures $1\frac{1}{2}$ in. x 4 in. x 7 in. The wire was crimped into a spring $\frac{3}{8}$ in. diameter, giving thirteen turns to the inch, and in each inch of spring there are $1\frac{1}{2}$ ft. of wire. There are ten separate coils, in two rows of five coils each, one row above the other. The various terminals are brought out to brass plugs in a fiber disk and contacts made successively with the various coils by the dial switch.

Worcester Polytechnic Institute.

FIG. 4—HEATING CURVE OF FURNACE

The Development in the United States of the Manufacture of Products Derived from Coal

A paper read at the Baltimore meeting of the American Institute of Chemical Engineers, on January 12, 1916.

BY H. W. JORDAN

During 1915 we read statements in the press almost daily which gave the impression that our American chemical industry was wholly unable to manufacture synthetic coal products, and that the only relief in sight was from the wonderful discoveries of a small group of chemical amateurs, who, having patriotically hurled themselves into the situation since the war began, were on the verge of evolving the entire 900 synthetic coal tar dyes and the whole list of pharmaceuticals from palmetto and other sources, hitherto unsuspected as being fundamental to organic chemical products. These statements, by implication, and by omitting mention of the extensive plants erected and put into operation by the old, established chemical companies in 1915, tended to create the public belief that these companies were doing nothing to supply the American market.

Some of the most important products which were widely heralded as having been produced for the first time in America in 1915, were manufactured by these companies 15 to 30 years ago. Benzol and its homologues have been regular American products, with shipment in carload lots or tank cars, and with occasional exportation to Europe, since 1900. Salicylic acid was manufactured at Jersey City by Zinsser & Company from 1880 until 1897, when foreign competition closed the plant.

SYNTHETIC CARBOLIC ACID

Synthetic carbolie acid was manufactured by the Semet-Solvay Company from benzol at Syracuse in 1900 and the following years, in quantities up to 2500 lbs. daily. This carbolie acid was synthesized into trinitrophenol, commonly known as picric acid, which was bought by the United States Government for use in national defense. The United States had several well equipped plants, prior to 1885, for manufacturing the principal coal dyes of that day. The industry grew, and produced an increasing number of synthetics, from which all those survive which could surmount the natural and artificial barriers in the road to a complete American coal products industry. The principal ones of these manufacturers have continued without interruption, and constitute the main body of our present organic chemical industry.

The failure to give credit in the daily press for the large amount of capital invested, and for the extensive work accomplished during the past year, is not fair to these American companies which built up our great American chemical industry during the past 30 years, and who are now the prime movers in expanding our American coal products industry to meet the new conditions.

The Benzol Products Company is an example of this growth. Organized in 1910 by men long associated with the acid, alkali and coal products industry, it began the manufacture of aniline and aniline salt at Frankford, Pa., in the aniline plant operated several years before by the late Dr. Jayne. Although the company's output of aniline in 1910 was but a small percentage of the American consumption, the English and German producers immediately dropped the price from 10c or 11c per lb., where they had held it for several years, to 9c or 8c per lb.

Most of the American consumers of aniline refused

to buy this American aniline at the fair price of 9c to 10c at which it was offered. Instead they followed their usual custom and sacrificed the American producer by supporting the cut-rate foreign producers.

These American consumers were the very ones who rushed to Washington when the war began, and frantically implored the Department of the Interior to dig up right away, quick, through the Division of Mines, some unfailing source of supply to provide the two thousand or more synthetic coal dyes and pharmaceuticals which had required 45 years of German science and organization to develop. The trip to Washington was easy for them. They had been there repeatedly since 1880, whenever a tariff bill was under consideration, to advocate no tariff on dyes.

The Benzol Products Company received the support of a few of the most far-sighted American consumers, who realized that the permanent establishment of aniline manufacture in the United States was of far greater value than the profit for a few years on their purchase of aniline, at 2c per lb. below its former price. With their support the manufacture of American aniline was continued.

Since the war, a new plant was built at Marcus Hook, Pa., and put into operation in August, 1915, with ultimate capacity equal to the former United States consumption of aniline. Notwithstanding war conditions, which multiplied the price of its raw materials, benzol, sulphuric acid and nitric acid, the company sold its aniline at a price less than half the prevailing market price of aniline, during 1915.

This production of aniline, supplemented by that of a few other plants, has supplied the American market to a fairly comfortable extent.

The Benzol Products Company's aniline has been distributed, by preference, to those consumers who employ directly or indirectly the greatest number of people. The important fact is that in 1916 a supply of aniline equal to the former American consumption will be available at fair prices, and that this supply is not coming from mysterious nor untried sources.

BENZOL SUPPLY

Since 1900 the production of benzol has steadily increased in the United States, so that there was enough benzol at all times for the manufacture of dyes, if the industry had been established by the assistance of the federal government and by the sustained support of the American textile manufacturers. Not only were both these lacking, but the textile manufacturers persistently favored the English and German producers in preference to any American manufacturers.

Benzol supply is only one factor, and alone it is not sufficient to justify the very heavy investments required to establish an American coal products industry.

In 1915 several steel companies operating by-product coke ovens, installed benzol recovery plants, so that a heavy production of American benzol is assured. When the war ends the output from these plants will be so abundant that it may become available as motor fuel for automobiles. In this service, 1 gallon of motor benzol gives 15 per cent greater mileage than does 1 gallon of gasoline.

ACIDS AND ALKALIES THE FOUNDATION OF COAL PRODUCTS INDUSTRY

Under the abnormal conditions and inflated prices caused by the war, many small plants sprung up and have produced products derived from coal at a profit. At the end of the war these plants will fall like autumn leaves. A few will struggle on and consume their war profits in hopeless endeavor to establish permanent busi-

ness. Only those built on a firm economic basis will survive.

The manufacture of products derived from coal is not an industry by itself. It is founded upon, and is an extension of, the manufacture of mineral acids and alkalies, and was created as a means of making a wider market for those acids—sulphuric, nitric, hydrochloric, acetic, for chlorine and the like and a market for the alkali products, soda ash and caustic soda. For this reason a permanent coal products chemical industry cannot be created in America except by co-operation with, or extension of, the American acid and alkali manufacturing companies.

THE VALUE OF EXPERIENCE

In 1915, with prices ten to fifteen times normal, it was possible to manufacture some coal products with large profit in the United States. With the return to normal conditions, we must conduct our processes with keenest attention to the most scientific methods, because losses of 1 per cent or 2 per cent in the steps of manufacture mean bankruptcy.

Proof that Americans sadly lack this scientific detail was given in 1915 by the many serious accidents, fires and explosions in plants manufacturing these products, the cause of which was faulty engineering design, inexperienced superintendence, untidy plant housekeeping and careless workmen.

With unconscious humor, we have done homage to German efficiency by ascribing these accidents to the German diplomatic service.

To illustrate the necessity of attention to detail, take synthetic manufacture of carbollic acid. This process, starting from pure benzol, involves five chemical reactions and from ten to fifteen chemical operations, if all by-products be recovered. If an avoidable loss so small as 1 per cent or 2 per cent be permitted in each of these steps, the final yield of carbollic acid would be so low that the process might be a commercial failure. Yet carbollic acid is one of the most simple products to manufacture.

Many others involve more steps, or steps in which the lack of technical skill produces larger loss. For example, a certain product with a normal price of 30 cents per pound has a possible maximum yield of 100 units attainable by extreme care in manufacture. With moderate care the yield drops to 88 per cent, and with ordinary care the yield drops to 75 per cent. Expressed in dollars and cents the result per ton is:

Possible yield, 100 per cent, 2000 lb., at 30c.....	\$600.00 per ton
Usual yield, 88 per cent, 1760 lb., at 30c.....	528.00 per ton
Common yield, 75 per cent, 1500 lb., at 30c.....	450.00 per ton
Loss, at 88 per cent.....	72.00 per ton
Loss, at 75 per cent.....	150.00 per ton

NATIONALIZATION OF THE INDUSTRY

Approach to 100 per cent technical efficiency is not the only requisite for commercial success. The intricate processes yield numerous by-products. Some are acids and alkalies which must be recovered and returned for use in the process. Others are salts or coal products which must be refined and sold. For many of these no market exists in the United States.

A network of markets must be created for every one of these by-products, either in the United States, in South America, Asia or Europe, if our American coal products industry is to grow with the world and pay reasonable dividends on the investment.

It is not sufficient that American consumers acquire the habit of buying chemicals "made in the United States." Our chemical industry, to endure, must cover the world's market; indeed, its ultimate success may depend upon an American merchant marine.

The German system of nationalized industry handles this multitude of by-products with military precision, by fitting each one into the particular technical and commercial chink best suited to it, so that all by-products are marketed at or about cost. This permits the main product to be sold at a profit large enough to sustain the normal growth of the plant and to develop new products, without adding new capital, and in addition to pay 10 per cent to 25 per cent dividends.

In complete contrast it has been, and is, the policy of our federal government to forbid any such interlocking national co-operation.

NATIONAL DEFENSE

The coal-products chemical industry is vital to national defense. One source of the extraordinary military strength of Germany is her ability to manufacture ammunition, literally from the air and earth, in unlimited quantity. This ability was created by the chemical industry, which built huge works and trained an industrial army of men with the scientific knowledge and technical skill necessary to transform the nitrogen of the air, and certain ones of the coal products, into ammunition. The fundamental reason for the support which the Imperial Government gave to the coal-products industry was that Germany should develop a supply of ammunition adequate for national defense and world conquest.

While developing home resources, the German industry bought benzol, carbollic acid and other crude coal products from England, thus absorbing England's commercial and military strength. Meanwhile we were more backward than England, for we were so quick to grasp the red-hot opportunity presented by German dyes and pharmaceuticals at low prices that we did not even take the trouble to produce enough crude coal products to export.

Ammunition cannot be manufactured in sufficient quantity during the interchange of diplomatic notes prior to war; it must be manufactured and stored long in advance of hostilities. One main national defense is that great coal-products chemical plants be established and operated steadily at commercial profit during peace, so that they will be instantly available to produce unlimited ammunition during war.

In 1915 we built many ammunition plants in the United States, every one on an artificial basis; few of them can make a profit at peace prices. Unless the United States establishes a complete and profitable national coal-products industry on a basis to keep abreast with all scientific progress, our program of "National Preparedness" will descend to the plane of comic opera.

NITRIC ACID FROM THE AIR

Nitric acid from the air is one step in such scientific progress. Our supply of nitric acid comes now from nitrate of soda imported from Chili. After the war, if the importations are not obstructed, we will receive nitrates and nitrogenous products manufactured in Norway and Germany by fixation of atmospheric nitrogen. Part of these products will be for fertilizer, part for explosives.

Exhaustion of the nitrate of soda mines in Chili will ultimately make the United States wholly dependent upon this European supply, unless we manufacture our own nitrates and nitric acid from the air.

The potash situation is a parallel condition. With German potash cut off, we have no potash. Various American sources will be brought into operation, but several years must elapse before we produce all the potash we consume.

Fixation of atmospheric nitrogen as nitric acid will also require several years, even though the Federal Government give the manufacture its strongest support.

Nitric acid is the effective end of every explosive and is the first chemical reagent used in the manufacture of aniline, and thence of indigo and others of the most important coal products and dyes. Without nitric acid, our entire navy, army and coast defense becomes helpless the instant the stock of ammunition is exhausted.

Our entire investment in national preparedness will be wasted money, if it does not include the manufacture of nitric acid from the air on a scale to render us absolutely independent of foreign nitrates.

TARIFF

A reasonable tariff, if formulated upon rational lines, will be of much value in supporting our coal-products manufacture. Such a tariff would divide these products into three classes according to their degree of advancement in manufacture, and would levy duties proportionate to this degree. The classes would be, first, crude products; second, intermediates; third, dyes, pharmaceuticals and highly refined products. The duties should be: On crudes, 10 per cent ad valorem; intermediates, 20 per cent ad valorem, and dyes, 30 per cent ad valorem.

If a specific duty be included it should be at the rate of 3¾ cents per pound on the intermediate class and 7½ cents per pound upon dyes and pharmaceuticals. There should be no specific duty on crude products.

The free list should include coal tar, coal-tar pitch, creosote oil and mineral acids. Natural indigo and other natural dyes of vegetable or animal origin should be placed with synthetic dyes, in class three.

Class 1—crude products—should comprise a small list. It should be described as: all crude products of coal produced through destructive distillation of coal, or otherwise, and not refined by more than one distillation, nor refined by any process other than distillation, nor refined nor produced by synthesis; such products being crude light oils, benzol, toluol, xylol, cumol and naphthalin, crude-tar acids containing less than 80 per cent pure-tar acids, and all other products from coal not otherwise specially provided for, and not medicinal and not colors or dyes, the duty to be 10 per cent ad valorem.

The second, or intermediate class, should include all products manufactured from those of the crude products class, and all so-called intermediates, not colors nor dyes nor pharmaceuticals nor medicinal products, such products being phenol, cresol, aniline, anthracene, etc.—duty 20 per cent ad valorem and 3¾ cents per pound specific.

The third class should include all colors or dyes derived from coal, including indigo, natural and synthetic, and alizarine—dry or suspended in water—and dyes obtained from indigo or alizarine, and all products derived from coal, which are used for pharmaceutical or medicinal purposes, or other purposes—duty 30 per cent ad valorem and 7½ cents per pound specific.

Natural indigo and all dyes, pharmaceuticals and medicines, and all other products derived from natural sources of vegetable or animal origin, and which are used interchangeably with similar products derived from coal, should be included in class three.

ANTI-DUMPING CLAUSE

There should be an anti-dumping clause to prevent unfair competition instituted for the purpose of destroying American industry. A dumping clause must be drafted with utmost care and its working tactfully handled. If it be too drastic, or if handled without

good judgment, it will become worthless, or worse, because foreign countries, in retaliation, will inflict the anti-dumping penalty upon any American manufacturers who may sell their goods in those countries at lower prices than in the United States. We cannot afford to take any chances with American industry now when our export trade in manufactures is becoming better established than ever before in our commercial history.

COMPULSORY WORKING OF PATENTS

Compulsory working of patents looks attractive in theory. In practice there has been nothing in the history of the coal-products industry which could have been changed or improved by it to the slightest degree. Compulsory working of patents has been tried in England, France and Russia as recently as 1907, and proved a total failure in those countries.

As stated by the German authority, Prof. Otto N. Witt, "the success of a coal-tar-dye factory is no longer dependent upon the careful guarding of factory secrets as in the past, but upon a systematically arranged plant and the proper distribution therein of the work to be performed, and above all upon skillful commercial management, both within and without the factory."

LACK OF TECHNICAL COMMON-SCHOOL EDUCATION

Lack of technical common-school education is a further disadvantage from which we suffer. Our system of early nineteenth-century education includes no technical or trade schools, by which in Germany the entire population is perfected in twentieth-century methods for earning their living in twentieth-century industries. In consequence American labor does not give effective attention to its job, and it is extremely difficult to secure labor in the United States which will give competent attention to the delicate chemical manufacturing operations of the coal-products industry.

In summary, the essentials for creation in the United States of a complete industry in the manufacture of products derived from coal are: Co-operation of the American acid and alkali manufacturers with the coal-products industry; co-operation of the American consumers with American products through long-term contracts to assure us the American market; establishment of the industry on a peace scale big enough to make it a fundamental factor in national defense; establishment on a profitable commercial basis of the manufacture of nitric acid, by fixation of atmospheric nitrogen; nationalization, or rather internationalization, of the industry to insure a balanced world market for all by-products; development of a system of twentieth-century common-school and technical-school education, and finally maintenance of a rational tariff.

That a larger coal-products industry will be established in the United States is certain. The degree to which it attains perfection will be in proportion to the extent with which these requirements for its profitable operation are provided.

Semet-Solvay Company,
Syracuse, N. Y.

The Canadian Mining Institute will meet in annual session at Ottawa, March 1, 2 and 3, 1916. Professional and business sessions will be held on the first two days, and the annual dinner will be held on the evening of the second. The third day will be devoted to a series of excursions to points of interest, including the mint, the Victoria Museum, and the Government ore-testing laboratories. The professional sessions will be marked by several important symposiums on various subjects, among which are flotation and mining education. Prof. J. W. Bell will present the results of ore-crushing experiments at McGill University.

Presentation of Perkin Medal to L. H. Baekeland

Report of Proceedings, Presentation Speech by Dr. Chandler,
Speech of Acceptance by Dr. Baekeland

On the evening of Jan. 21, in Rumford Hall of the Chemists Club of New York, amid beautiful decorations of roses, in a lavish setting of flags, bakelite products and velox photographs, before a very large, enthusiastic and representative assemblage, the Perkin medal was formally presented to Dr. L. H. Baekeland.

Dr. WM. M. GROSVENOR, chairman of the New York section of the Society of Chemical Industry, presided. In his introductory remarks he sketched the scope and the history of the Perkin medal, which is annually awarded for most distinguished service in industrial chemistry by a joint committee of the different American chemical societies.

Dr. CHARLES F. CHANDLER, the beloved dean of chemistry in America and senior American past-president of the Society of Chemical Industry, made the formal presentation speech in his happiest mood.

Dr. L. H. BAEKELAND accepted the medal in a few words of thanks, full of deep feeling.

Two deliciously informal speeches were then made by men with whom Dr. Baekeland had been closely connected in his professional career. Mr. RICHARD A. ANTHONY who had given Dr. Baekeland his "first job" in America as a photographic chemist, expressed his delight of having finally found out the secret of velox—that washing can be overdone. He recounted various instances from later life in which he had consulted Dr. Baekeland, in different chemical projects, the advice given always turning out right.

Mr. ELON HUNTINGTON HOOKER, president of the Hooker Electrochemical Company, followed with an exceedingly clever speech, recalling the early days when the Townsend cell was being tested out on a semi-commercial scale:

In this Republic, when offering the highest laurels, we delight to trace back the connection, with humble associations, of him we honor. So it is characteristic to wish to link this occasion with the amusing, but, none the less, highly dramatic and serious incidents of Dr. Baekeland's intervention in the original testing of the Townsend Process in commercial units. Imagine, if you can, a wing of the Edison power station in an altogether disreputable section of Brooklyn. Two full-size Townsend cells, erected with necessary supply tanks, exhaust chimney, etc., producing chlorine in juxtaposition to the valuable generating units of the Edison Company. Upon these the lighting and transportation conveniences of the "city where we sleep" are dependent.

Picture further, three young men, who did not know chlorine gas from ottar of roses, or caustic from lemon ice, but of undoubted bravery, assisted by negroes whose only aim was Saturday night's pay and the hope of a possible bleaching,—picture them, guided sporadically by Townsend and Sperry, but presided over, their drooping spirits revived, and their hope of heaven determined, by the genius of Baekeland. He, you understand, had just been rescued from the depths of photographic invention, with its spirit-dulling materialistic opulence, and uplifted to the rare delights of electrolytic research—that shadowy borderland between pure science and commercialized industry where

mathematics and chemistry join hands in the great unknown.

Here our friend held forth long hours in shirt-sleeved efficiency, while his social reputation became tainted, his domestic status strained, and his short nights of peace in Yonkers, even in Harmony Park, were rent with agonized appeals for help from Brooklyn at 3 o'clock in the morning: "Cell No. 1 has broken down; the place is full of chlorine gas; we are all out in the street; the Edison boss says his \$100,000 generators are being eaten by a green substance. What shall we do?" Answer:—punctured with picturesque speech: "Start it up, of course. I will be over before breakfast."

Or again: "Cover cell No. 2 has blown off from hydrogen pressure. What would you do?" Answer:—in voice choked with sleep, or deep emotion, and clothed in pajamas: "Put on a new cover and have the darkey sit on it until I can get over in the morning."

That Brooklyn equipment had been timed with all the nicety of shrapnel. Exhaust fan and stovepipe chimney resisted the chlorine until a mere shell, and then, like the "wonderful one hoss shay," crumbled into a mass of iron dust the last day of the test. The Edison janitor shoveled us into the street and, like a true homeopath, disinfected the place from garret to cellar with drums of chloride of lime.

Mr. Hooker then spoke of Dr. Baekeland as a man. "You all know his multifarious activities; a helping hand here, a word of inspiration there, a cheery hand grasp, with wisdom dissolving away technical difficulties; speech clean, from a heart that thinks no ill of others, the standard of professional ethics carried high where all can approve, and a breadth of scientific grasp

and knowledge which illumines whatever his swift mind plays upon. We, his friends, lack the proper perspective to do him and his work justice. Time alone can furnish that."

In conclusion Mr. Hooker pointed out how Dr. Baekeland "has put his faith and his life into American institutions, until he stands, known of all men, as one of the best Americans—one whose enthusiasm, patriotism, and love of his adopted country takes us back to the Americans of an earlier day. It is thus I like best of all to think of him."

The proceedings were concluded by Dr. Baekeland's long and very interesting, instructive and suggestive formal speech of acceptance which truly fascinated his audience.

Twice during the proceedings Mrs. Baekeland's name was mentioned. First, when Dr. Grosvenor in his opening speech referred to the floral decorations "for which we have to thank one who has had very much to do with the genial success of Dr. Baekeland—Mrs. Baekeland." Again, when in his address of acceptance Dr. Baekeland spoke of his university days in Belgium, he said that one of the most fascinating discoveries he then made was the fact that his senior colleague in the chemical department had an unusually attractive daughter and that this discovery led a few years later to the most interesting and successful experiment of his life.

L. H. BAEKELAND

We herewith publish in full the two formal addresses of Dr. Chandler and Dr. Baekeland:

Presentation Address

BY PROF. C. F. CHANDLER

Mr. Chairman and Brother Chemists:—It is my privilege and very pleasant duty, as Senior Past-President of the Society of Chemical Industry, residing in this country, to present to Leo Hendrik Baekeland, B.S. and D.Sc., the tenth impression of the Perkin Medal, in recognition of his most original and valuable work in applied chemistry.

Dr. Baekeland was born in 1863 at the old Flemish city of Ghent, where he received his early education. He passed through the elementary schools, the Athenaeum, a Government High School, where he prepared for the University, and the Ghent Municipal Technical School, which resembles our Cooper Institute.

In 1880 he entered the University, where he studied various natural sciences, specializing in chemistry. Although the youngest student in his class, seventeen on entering, he promptly won his degree of B.S. and later, when 21 years old, the youngest graduate, he received his degree of Doctor of Science, passing his examinations with the highest honors.

Dr. Baekeland must have been as industrious while a student, as he has been since he graduated, for from the age of seventeen he supported himself entirely by tutoring and as lecture assistant.

Later he was appointed assistant professor, and in 1889 associate professor at the University of Ghent.

In the meantime, in 1887, he had been appointed professor of chemistry and physics at the Government Normal School, then existing in the city of Bruges.

In a competition among the alumni, who had graduated from the four Belgian universities during a preceding period of three years, he was awarded the first prize in chemistry, by a jury of the senior professors of chemistry of the four universities: Theodore Swarts and W. Spring for the Government Universities of Ghent and Liege; P. De Wilde and Louis Henry for the Universities of Brussels and Louvain. The president of the jury was Jean-Servais Stas, best known by his classical researches on the atomic weights.

This prize, besides a gold medal and other rewards, entitled him to a traveling scholarship, by which he was enabled to visit some of the universities in England, Germany and Scotland, and to make a trip to the United States in 1889.

I have given you these details of Dr. Baekeland's early life, because I believe few, if any, of you were familiar with them; because they are most creditable to him, and show his personal character, and because I knew he would not disclose them himself.

Before leaving Ghent, he had become deeply interested in photography. Since the early eighties Ghent had become a center of the new industry of dry-plate manufacturing, started there by Dr. Van Monckhoven.

Dr. Baekeland was an enthusiastic amateur photographer, and had followed every step of the new processes, with the result that he acquired some reputation in this new branch of chemical industry.

On his arrival in New York, he became acquainted with Richard A. Anthony of E. and H. T. Anthony & Co., with whom I had been associated for some time as editor of their photographic bulletin. Richard Anthony brought us together, and I think it was a case of love at first sight, for we have been the very best of friends ever since.

The Anthony firm, which later joined the Scoville Company in establishing the Ansco Company, had engaged in the manufacture of photographic films and bromide paper, and they offered Dr. Baekeland an ex-

cellent position as chemist in their factory, an offer which he promptly accepted, deciding to remain in the United States.

The Minister of Education of Belgium, in accepting his resignation, paid him the unusual compliment of authorizing him to retain the honorary title of "Associate Professor at the University of Ghent."

After two years, he left the Anthony firm and established himself as a consulting research chemist, and devoted himself to developing several chemical processes which he had devised.

In 1893, in partnership with Mr. Leonard Jacobi, he founded in Yonkers, the Nepera Chemical Company, where he started very modestly the manufacture of various kinds of photographic papers. One of these papers, which was called "Velox," has since earned a great reputation as a photo printing paper.

Dr. Baekeland had worked to perfect this paper as far back as 1883, while he was still a student in Ghent, but its importance as a possible subject for a commercial enterprise did not become apparent to him till much later.

Silver-chloride emulsions had been proposed and described in 1891 by Eder and Pizzighelli, but their process was carried out along the same general lines as silver-bromide emulsions, namely, precipitation and ripening, followed by washing to remove the soluble salts resulting from the reaction.

Baekeland had found that as far as chloride of silver emulsion is concerned, the last two operations, although they increased the sensitiveness of the emulsion, had a disastrous influence on the tone and general gradation of the image, specially in the shadows.

He had discovered that in order to keep these desirable qualities it was necessary to produce chloride of silver in a special colloidal condition, which is easily disturbed by any after treatment of the emulsion, as for instance, "ripening" or "washing."

By committing an act of "photographic heresy" in omitting the washing entirely, Baekeland found he could make a variety of colloidal silver-chloride which was relatively insensitive to the yellow rays of the spectrum, and therefore could be manipulated by candle or gas light, if not brought too near.

This made the paper incomparably inferior to bromide paper, or ordinary chloride of silver paper, as far as speed is concerned.

But Baekeland realized the important fact that by exposing quite close to the artificial light, and developing the image at a safe distance (a few feet) the apparent defect could be turned to a great practical advantage.

But the process had to be studied in all its endless details of manufacture before it could be carried out on a large scale, so that it could be standardized for use by the photographic public, which was no easy task.

The paper was put out in the trade under the name of "Velox," and met with very scant favor at first; in fact, it took years of education and hard work before the value of the process was fully recognized.

Then as soon as the first indications of success were apparent, several competitors started in the same field.

But after the value of the process was clearly recognized, it gained rapidly in popularity, and in 1899 the Eastman Kodak Company offered to buy out the entire business enterprise on very liberal terms, which were promptly accepted.

This relieved Dr. Baekeland from all further commercial worries, and placed him in a position in which he was free to live the life he had always ardently desired; in which he would be able to devote his time and energy to study and research, free from school, university and business cares.

Dr. Baekeland next turned his attention to electrochemistry. It was a new branch of chemical industry scarcely known in his early student days. Its field was limited then to the electro-deposition of a few metals from aqueous solutions, such as copper, nickel, silver and gold.

He was very much impressed by the wonderful expansion of the applications of electricity for chemical purposes in recent years, especially in the United States.

Charles M. Hall, a Perkin medalist, had brought out his beautiful and simple process for extracting aluminum from alumina, in 1886, and had given a practically new metal to the world to replace copper, tin and zinc in many arts.

Hamilton Y. Castner, a Columbia boy, had invented, in 1890, his simple process for making sodium a commercial metal, and simplifying the preparation of some of its most valuable compounds, as cyanide and peroxide; and in 1892 his ingenious process for making pure caustic soda and chlorine from salt.

Edward Goodrich Acheson, a Perkin medalist, in 1892, had discovered carborundum, and devised a simple process for producing it in unlimited quantities, and in 1895 had devised his process for the manufacture of artificial graphite, which he followed later, in 1906, with the invention of that remarkable and useful substance, "deflocculated graphite."

Thomas L. Willson had, in 1899, devised a process for producing in unlimited quantities crystalline calcium carbide, which by the action of water creates acetylene gas, and by the action of nitrogen from the atmosphere, produces the new and most valuable atmospheric fertilizer, "calcium cyanamide."

There are two facts which make me linger here with pleasure: every one of these inventions was made by an American chemist, and every one of them resulted in the establishing at Niagara Falls one or more large works, where the inventions are utilized by the use of electricity developed by the waters of Niagara.

These industries are financed, and most successfully worked by the Aluminum Company of America (Hall's aluminum); the Niagara Electro-chemical Company (Castner's sodium and cyanides); the Castner Electrolytic Alkali Company (Castner's caustic soda and chlorine); the Carborundum Company (Acheson's carborundum); the International Acheson Graphite Company (Acheson's graphite and deflocculated graphite), and the Union Carbide Company (Willson's calcium carbide).

Who can question the ability of American chemists to make original researches and devise new and useful processes? These are not all, by any means; they are merely examples which I have selected because I am most familiar with them.

Dr. Baekeland was very much impressed by these developments, and decided to enter the electrochemical field. So he spent a winter at the Technological Institute at Charlottenburg, near Berlin, in the electrochemical laboratory, to freshen up his knowledge of the subject.

On his return to America he equipped a modest private laboratory on his grounds at Yonkers, and provided it with a few electrochemical appliances for further study.

His work drifted in many other directions, but about that time Mr. Clinton P. Townsend had just invented his now famous electrolytic cell, for producing caustic soda and chlorine from salt. Baekeland was requested by Mr. Elon H. Hooker to take the direction of the work preliminary to the industrial development of this invention. This he did in company with the inventor and several other skilled experts.

The work finally resulted in the formation of the

Hooker Electrochemical Company, and the erection at Niagara Falls of one of the largest and best equipped electrochemical plants in the world, with which he is still connected in an advisory capacity. In this connection he took out his first two patents, "apparatus for regenerating electrolytes," and "an electrolytic diaphragm and method of making same."

BAKELITE

Dr. Baekeland's crowning work is the solving of the mysteries involved in the action of formaldehyde upon phenols, and giving to the world the new material "bakelite."

Bakelite is a so-called condensation product of phenol—or carboic acid—and formaldehyde. Instead of phenol, its homologues, cresols or other phenolic bodies can be used. Instead of formaldehyde, other substances which have the same functions may be utilized, as, for instance, methylal, paraform and hexamethylenetetramine.

It should be well understood that formaldehyde in reacting upon phenol does not necessarily give bakelite. Quite to the contrary, it is only under very special conditions, now well established by the published research work of Baekeland, that this substance can be obtained.

In fact, when formaldehyde is let to react on phenol under ordinary conditions, almost anything may happen but the formation of bakelite.

There are very few examples where the same two substances, reacting upon each other, can give such a variety of products. For instance, a nicely crystalline substance, called saligenin, or oxybenzyl-alcohol, found in the willow-tree (*Salix*), may be the result. This substance has been used in medicine, and is known also as diathesisin.

In other cases, a resinous material is formed, but it has no specially new properties and is very similar to cheap, natural resins. For instance, it can be melted and dissolved rapidly just like any other natural resin, and neither its hardness nor other general properties give it any special claim above the natural resins.

This is the substance which has been called novolak, and which has been prepared by Blumer and others; it has never found any serious applications as such, although at one time it was expected that it would be useful as a shellac substitute, when the price of shellac was unusually high.

It is generally known that as far back as 1872 Adolf Bayer and his pupils (Ber., 5, 1095; 19, 3004; 25, 3477; 27, 2411) showed that it was possible to obtain condensation products of *aldehydes* and *phenols*. These experiments, at this time, were not conducted with formaldehyde, because formaldehyde, as such, was not obtainable, so the reactions were mostly conducted either with the methylen representatives of formaldehyde or with the then available acetaldehyde.

The substances studied at that time varied considerably in character and embraced more particularly certain crystalline, well defined products. Now and then some uncrystallizable substances were obtained, but no special attention was paid to them, nor had they much in common with the present product, except that they had a resinous appearance.

About 1891, formaldehyde was put on the market as an article of commerce, and Kleeberg (*Annalen*, 263, page 283, 1891) tried to repeat some of the work of Bayer by using formaldehyde, in presence of strong hydrochloric acid. He thus obtained a worthless, irregular mass, which he attempted to purify by the usual methods and bring to a constant composition, but he did not succeed, so he dismissed the whole subject and continued his studies of phenolic condensation products along other lines which enabled him to prepare well

defined crystalline substances which have nothing to do with the present subject, except the origin of the raw materials.

Others, like Smith, Luft and Story, took up the same subject, using formaldehyde, endeavoring to master this reaction either by the presence of solvents, which were partially eliminated afterward, or by the introduction of foreign substances like camphor. But none of these processes developed into anything on which an industrial enterprise could be founded with any chance of success.

In the meantime, Blumer and De Laire had described methods by which formaldehyde and phenol could be made to produce, with certainty, special resinous substances which were entirely analogous to the natural resins, like shellac, copal, etc., of which they had practically all the general properties; that is to say, they were fusible, they could be melted, they could be dissolved in suitable solvents. These processes were calculated carefully to avoid the formation of anything but these fusible and soluble products, on which they built great hopes as possible substitutes for shellac.

If the methods of preparation described by these inventors are not carefully followed, then it happens frequently that disturbing side products are produced. The latter, instead of being easily fusible and soluble, are irregular masses of the Kleeberg type containing variable amounts of infusible and insoluble substances which are of no value for further purposes, because you cannot do anything with them after they are once formed. These are exactly the substances which Kleeberg had rejected on account of their negative properties.

This was the state of the art until Baekeland made the disclosure of his own work. He was particularly attracted by the failure of Kleeberg and hoped to find a suitable solvent for his worthless product. It occurred to him that if he could find a solvent for this material he would be able to make a varnish superior to all existing varnishes. The difficulty was to find the solvent.

His assistant, Mr. Nathaniel Thurlow, felt very skeptical about it and pointed to the unsuccessful attempts of others, after trying most of the available solvents. The fusible, soluble resins of the Blumer and De Laire type seemed considerably more attractive.

But Baekeland took the point of view that their qualities were not better than those of the natural resins. In fact, in practical tests on a large scale, he had found that in many respects their qualities were inferior to those of shellac, which, furthermore, could be purchased at a more advantageous price than the cost of production of these synthetic resins.

So he concluded to purchase or prepare further solvents of every kind so as to determine whether he could not do something with the substance of Kleeberg, and finally, after many renewed attempts, he had to give it up as a hopeless task.

Then he changed his tactics. He reasoned that if nothing could be done with the substance after it was once produced in a flask or any other vessel, he should attempt to carry out the reaction so as to generate the substance right on the spot where he wanted it. For example, he thought that if he could make the synthesis inside of the fibres of wood by injecting first the two reacting raw materials, and then start the reaction, he might be able to incrust the fibres of the wood with an unusually hard and inert substance, and give to the wood new properties.

This was easier said than done. He encountered endless difficulties. Certain classes of wood, specially the higher grades, instead of becoming harder, became softer. He also noticed that chemical reactions in these

capillary conditions proceed in a very different way than in a flask or other container, for the reason that the chemical dynamics in capillary spaces are considerably disturbed, so that the reaction which may terminate rapidly and completely in a wide vessel, will be considerably hampered when the mobility of the reacting molecules is disturbed by capillary conditions.

He also perceived that, just on this account, the carbo-lic acid, before it had time to react upon the formaldehyde, had every opportunity for destroying the fibre. He concluded that in order to have any success, he should either be able to speed up the reaction by some special means, or he should find a way whereby he could partially start the reaction outside of the fibre of the wood in a flask, and finish it afterward within the tissue of the wood, after injection.

This led him to a long systematic investigation, when he tried to study all the different factors of the reaction. When he was through with this line of research he had established practically all important facts on which is based the foundation of the present industrial processes of bakelite.

He found that under certain conditions he could dissect the reaction in different succeeding steps, where one of the first steps was the production of a certain intermediary substance which, although it had the general appearance of a resin on account of its brittleness, its solubility and its fusibility, differed radically from the natural resins by the fact that as soon as he heated it at a certain temperature above its melting point, it changed into an entirely different body incomparably harder and stronger than the original resinous material, and which, furthermore, looked like natural amber although it was much stronger than amber, and had another advantage over amber or similar resins, in the fact that it did no longer melt if heated, and that it was insoluble in all known solvents.

He also established the fact that in the different reactions which engendered this substance, there is one phase where polymerization occurs and that this phase is accompanied by self-heating, which brings about a considerable rise of the temperature of the mass, so that whenever any attempt is made to hasten this part of the process which produces hardening, the self-heating becomes so exaggerated that gaseous products are evolved, which blow up the mass and cause porosity, which makes it worthless. In order to offset this, he introduced, besides other means, the use of a very strong counter-pressure during the period of polymerization.

He discovered also the important fact that the presence of ammonia, or another base, in suitable proportions, will surely make the reaction go the right way toward the production of the infusible product, while with the presence of an acid, the formation of permanently fusible resins will be favored in case the amounts of carbo-lic acid are preponderant; that furthermore, the use of a suitable base in proper quantities gives an easy means of controlling the reaction at whatever phase is desirable. From then on, it became possible for him to avail himself of practical means for preparing, as a starting point, an initial condensation product which was still fusible and plastic, and do with it whatever he pleased while it was still in that initial condition. For instance, he could mold or form it or dissolve it, and then afterward, under the action of heat, polymerize and harden it to the final condition of maximum hardness and strength, where it is no longer fusible or soluble after it had acquired its permanent shape.

The initial bakelite is designated usually as bakelite A; before it is polymerized, it dissolves and melts to a liquid; but this liquid has the strange property of

"freezing" when sufficiently heated and then afterward can never again melt or dissolve; it has been "polymerized" into bakelite C.

It should be pointed out here that ammonia, in conjunction with formaldehyde, gives a chemical which is called hexamethylenetetramine, and that the action of ammonia in presence of formaldehyde in this process is entirely similar to that of the use of hexamethylenetetramine.

It was found also by him that the mechanical properties of these infusible condensation products were enormously improved by the introduction of fibrous substances, as for instance, wood fibre or asbestos. All pulverulent fillers which are successfully used in conjunction with other plastics, instead of improving bakelite, make it worse. This is due probably to the fact that bakelite, although it has an unusually high tensile strength, has a relatively low degree of elasticity which makes it sensitive to impact and shock. The introduction of fibrous materials into bakelite makes it enormously more resistant to shock than the pure article.

Many other facts were established by his work. For instance, it was demonstrated that among the homologues of phenol, it was not indifferent what kind of homologues is used. It so happens that ortho-cresol tends towards the formation of fusible products of low strength. Para-cresol also gives condensation products of very inferior qualities, while meta-cresol, or mixtures of meta-cresol and para-cresol, give the best product. This enables the use of some of the more available cresols, instead of expensive phenol.

He not only pointed out unmistakable methods for producing every time, at will, either a fusible or an infusible resin, but he gave the explanation why in one case one substance and in another case, a different one was obtained, when starting from the same raw materials. He established the theoretical relations and parentage of those different substances, all derived from the same raw materials and yet so different in their properties and technical uses. In this way, he established the relation between the crystalline product saligenin (oxybenzylalcohol) contained in the willow tree and how it is possible ultimately to convert it, at will, either into the fusible resin of the Blumer type, or into bakelite, by submitting it to further chemical reactions.

To sum up: Before he had published the results of his work, there existed not a single industry, nor a single application of any importance based on these condensation products. Since he has published his patents and read his papers before the American Chemical Society, there have been started here and in Europe numerous factories where these processes are used for the most varied purposes, ranging from the manufacture of a billiard ball to that of a wireless telegraphic apparatus; from the manufacture of a self-starter for automobiles to that of transparent fountain pens, this range of varieties embracing such articles as switchboards for battleships, moldings for kodaks, phonograph records, casings for instruments of precision, armatures and commutators for dynamos and motors, telephone receivers, railroad signals, grinding wheels, umbrella handles, buttons, cigar holders and pipe stems, articles of ornament, etc.

The General Bakelite Company has a very complete plant at Perth Amboy, where the raw materials are made; there are a large number of licensees in the United States; bakelite plants in Germany, France and England; and several factories in Europe where bakelite goods are manufactured under license, for example, two bakelite button factories in Germany and one in Russia.

It is absolutely impossible to tell the story of "bakelite" with any completeness in the time allotted to me, and I must refer you to Dr. Baekeland's articles and patents, where you will find everything fully set forth.

I have prepared a complete list* of the United States patents, arranged in the order in which they were applied for, as that order will enable you to follow chronologically this stupendous investigation.

There are many additional patents which have been allowed but not yet published, and many more which are now before the Patent Office.

It was at first thought by some persons that some of the early investigators, beginning with Adolf Bayer, whose names I have already mentioned, must have anticipated Dr. Baekeland in his discoveries and inventions. This is not the case; Dr. Baekeland's inventions, as described in his patents, are not anticipated.

The subject was most thoroughly tried out in the United States District Court, Eastern Division of New York, before Judge Chatfield, who rendered his decision in Dr. Baekeland's favor, in a most elaborate and lucid opinion, covering twenty pages of The Federal Reporter. His Honor clearly pointed out step by step the radical differences between the work of Baekeland and each one of the prior writers and patentees.

In closing I will call attention to the distinctions which Dr. Baekeland has had showered upon him, in recognition of his scientific standing and achievements in the domain of industrial chemistry: President Chemists' Club, 1904; vice-president Society Chemical Industry, 1905; chairman N. Y. Section American Chemical Society, 1908; president American Electrochemical Society, 1909; president American Institute Chemical Engineers, 1912; president Inventors' Guild, 1914. Official U. S. delegate to International Congress of Chemistry, London 1909; president Section of Plastics, International Congress of Chemistry, New York, 1912; first Chandler Lectureship, School of Mines, 1914; member Naval Consulting Board of United States, 1915. Nichols Medal, 1909; John Scott Medal, 1910; Willard Gibbs Medal, 1913; Chandler Medal, Columbia University, Fiftieth Anniversary School of Mines, 1914.

Leo Hendrik Baekeland, Doctor of Science, my dear friend: It gives me the greatest pleasure, as the representative of the affiliated chemical and electrochemical societies, to place in your hands this beautiful Perkin Medal, as a token of the appreciation and affection of your fellow chemists.

* * *

Address of Acceptance of Perkin Medal

BY DR. L. H. BAEKELAND

Mr. Chairman, Ladies and Gentlemen:—In accepting the great honor you are willing to bestow upon me, I realize at the same time how many of my fellow chemists have achieved much better work than anything I ever attempted. On this account, my feeling of gratitude toward you changes entirely into a sentiment of profound humility and arouses in me the ardent desire of endeavoring to do better in the future. Should I not live up to this resolution, then every time I shall look upon this medal, it will appear to me as a symbol of reproach instead of a token of merit.

And now, what shall I say further on this occasion? So much has already been told about me this evening that, if I could drop the whole subject right at this

*Dr. Baekeland's U. S. patents are \$44,314, 1906-7; \$55,221, 1906-7; \$43,671, 1907-10; \$42,699, 1907-9; \$42,852, 1907-9; \$54,666, 1907-10; \$42,809, 1907-9; \$42,808, 1907-9; \$1,057,319, 1907-13; \$42,700, 1907-9; \$39,966, 1909-9; \$1,054,265, 1909-13; \$41,605, 1909-9; \$1,019,408, 1909-12; \$1,160,362, 1909-15; \$1,160,365, 1909-15; \$1,038,475, 1909-12; \$1,246,045, 1909-15; \$67,137, 1909-10; \$1,057,211, 1907-13. The patents are given in the order of their application, the first date following the patent number is the year of application and the second is the year of issue.

point and go quietly home, I should feel intensely glad and relieved.

But the Perkin Medal Committee urges me to take this opportunity for explaining some of my experience as far as it relates to the handling of problems connected with new chemical enterprises.

Therefore, I can spare you a repetition of technical details about my work, which you have heard abundantly on other occasions, and which are now available in the chemical literature. I shall thus try to make this occasion serve a better purpose by presenting my point of view in relation to the chemical development of this country, and I hope that by the time I am through, I may have convinced some of my younger fellow-chemists that a reasonable measure of success in their chosen career is not such a difficult matter after all.

PRACTICAL LIFE AS A COMPLEMENT TO UNIVERSITY EDUCATION

Reference has been made by Professor Chandler to my early training. I feel very grateful for the excellent opportunities of education I had at the University of Ghent. I should state, however, that my real intense education only began after I had left the university, as soon as I became confronted with the big problems and responsibilities of practical life; this education I received mainly in the United States, where for twenty-seven years I was thrown in contact with so many varied subjects. I hope to remain until I die, a post-graduate student at that greater school of practical life, which has no fixed curriculum and where no academic degrees are conferred, but where wrong petty theories are best cured by hard knocks. There was a time in my life when, as a young teacher of chemistry, I was just as cock-sure as some of my older colleagues that everything was as simple as it appears in the textbooks. This lasted until I tried to make bromide of silver for commercial purposes in the preparation of photographic emulsions. Stas had already published the fact that there were three or four different varieties of bromide of silver, all of exactly the same chemical composition, yet differing in their physical properties. By the time I got fully engaged in the manufacture of silver-salt products for photographic purposes, I had come to the conclusion that instead of three or four varieties of bromide of silver, there existed perhaps a hundred varieties, but that of those hundred varieties, there was only one which might probably keep me from the poorhouse and assure me success as a manufacturer. And yet, until then, that unexciting chemical reaction which produces bromide of silver and which in our textbooks is expressed by such a simple chemical equation, always had appeared to me as hardly worth while of further investigation. By and by, I began to look at chemical phenomena from quite a different standpoint, and I well remember the day when I reasoned to myself as follows:

"Here is one of the very simplest of all chemical reactions, so simple that any chemist hardly wastes any time over it, and yet it involves phenomena so intricate, so varied in scope and effect, that we have not yet found the proper means to fathom them. Here is bromide of silver, freshly precipitated in the dark; it has the property of not darkening if brought in contact with a reducing agent—a developer—and yet the mere action of light, even for only an infinitesimal fraction of a second, brings about such a profound alteration in its constitution that henceforth it will blacken and set silver free if treated with a reducing agent, and thus produce a photographic image. Furthermore, this bromide of silver, before and after it has seen the light, is exactly the same, as far as we can decide by chemical

analysis or any of our other clumsy means of observation. Suppose now that the human race were not provided with the sense of eyesight—just as we probably are missing several other senses—we would forever remain unaware of that peculiar effect of light on silver bromide or on chemical reactions in general."

This gave me one of my first warnings not to accept any chemical explanation in too simple terms, and engendered in me the evergrowing belief that the very plainest chemical reactions are incomparably more complicated than our hasty generalizations in text-books lead us to believe.

It thus became my good luck that my early struggles with photographic problems cured me of too much confidence in easy explanations of chemical phenomena and made me lose somewhat that youthful overabundant faith in class-room theories. I suppose my experience is very similar to that of many an industrial chemist who has had to learn by sheer experience, that after he may think he knows everything on a certain subject, he is constantly confronted with endless matters of detail which at first seemed so trifling, alongside the broad lines of the subject, as to be unworthy of the attention of the theoretical chemist. And yet it is these details which frequently determine whether the practical solution of a problem is possible or not—whether the ruin or success of a chemical enterprise is in sight.

TOO MANY IRONS IN THE FIRE

Nor was it all plain sailing in my early days here in this country. Like so many others, I committed the mistake of scattering my attention on too many subjects at the same time. After I left the Anthony firm, I tried to work out, without sufficient financial means, several half-baked inventions, the development of each of which would have required a small fortune. Fortunately for me, I was taken out of this muddle and shaken to my senses by a very severe illness which nailed me to bed for several months. While I was hovering 'twixt life and death, with all my cash gone and the uncomfortable sentiment of rapidly increasing debts, I had abundant time for sober reflection. It then dawned upon me that instead of keeping too many irons in the fire, I should concentrate my attention upon one single thing which would give me the best chance for the quickest possible results.

Among many other matters, I had an electrolytic process for extracting tin, a safety explosive, and a new photographic paper. The tin process had lost all its charms since the swampy meadows of New Jersey, where I was carrying out my experiments, had brought me almost within close acquaintance of the undertaker. Nor did the manufacture of explosives appeal much to me after I had been for so many months in the hands of surgeons and physicians; so I turned to my old love, photography, ready to manufacture some new kinds of photographic paper.

THE HISTORY OF VELOX

I was lucky enough to make the acquaintance of Mr. Leonard Jacobi, of San Francisco, who was willing to risk some of his cash in my venture. He knew nothing of chemistry, nor of any technical matters, but he was a generous-minded, cheerful and very industrious man, who furthermore honored me with his implicit confidence. Although much of an idealist, he was in business matters very sober-headed and very careful and conscientious towards all the immediate problems before him, and I owe it to the excellent example of his common sense that I learned some of the practical rules of business life which afterwards came into good purpose in my future career.

Do not imagine that from the beginning of this enterprise everything went smoothly. Quite to the contrary. As luck would have it, we started this venture just at the very worst time, in 1893, during the famous business panic, when so many of the industries of the United States went under. In this instance, our salvation was that we had started on a modest scale and that whatever disadvantageous conditions we encountered, or whatever mistakes were committed, we could straighten up matters without too fatal a loss of capital.

We had more than our share of the usual technical troubles which accompany the starting of any new enterprise. It was found, for instance, that while we could make excellent paper in temperate weather, it became practically a hopeless task to do so in the hot summer days. Our sales were small and when we had any sales we were confronted with the problems of the climate and then our manufacturing methods were more or less like a gamble. This caused us considerable losses. The remedy seemed easy enough, so we tried to rectify the conditions of temperature by artificial cooling, as others had done. But this had not the required effect and new disappointments confronted us.

After awhile special scientific investigation disclosed the fact that the troubles were not due so much to the factor of temperature as the moisture in the air. This led us to install a refrigerating system over which the air could be drawn first so as to extract its moisture by precipitating it as ice, after which the dried air could be sent over heated pipes so as to raise its temperature to the proper degree before it entered in the paper-coating machine. At that time this seemed a rather paradoxical method of operating, but to-day it has been adopted by several large manufacturers of photographic papers and films. It was only many years later that I heard of the Gayley process for blast furnaces where a similar method is used for insuring the steady dryness of the air in the smelting of iron.

Manufacturers in Europe, where the amount of moisture in the air does not vary to such an extraordinary extent between seasons, have scarcely any conception of what difficult manufacturing problems are encountered here in the United States where in winter the air is so dry as to cause electric sparks and abundant static electricity by friction, while in the summer months the air is often so saturated with moisture that any objects or machinery condense humidity on their surfaces at temperatures as high as 76 deg. F. But I believe that it is just on this account that in some industries American manufacturers have been compelled to solve with more thoroughness and with more effective means, the greater difficulties they encounter here in the varying climatic conditions; this also is the reason why some of our industries have reached a higher degree of development and perfection than the corresponding European enterprises. The humidity in the air during our hot summer season, aside from the manufacturing problems, is very hard on photographic prints. Photographs made with inferior processes may give prints which last many years if kept in Europe, but it frequently happens that the same prints deteriorate here in a few weeks in summer time.

In the early nineties and following years, this country was using more and more photographic printing methods which consisted of the so-called combined-bath processes, and by which toning and fixing of the image was produced at the same time.

At that time, practically all manufacturers of new sensitized paper advocated this rather easy process. Few, if any, hesitated to promise permanency of these prints, and this on the strength that such prints had been preserved successfully in Europe. A rather simple

test gave me a method of distinguishing which kind of photographic prints were most likely to fade. This test consisted in cutting a photograph in two and exposing one-half in a jar to the fumes of ammonium-hydrosulphide. This treatment, in a few hours, showed the same amount of fading as would have been produced under ordinary conditions after months or years.

Upon the result of these experiments I had based the manufacture of several sensitized papers, which I could unhesitatingly recommend as giving permanent prints. One of these papers we called *Velox*, on account of the speed with which the prints could be made independently of weather conditions. In this process prints are exposed for a short time to artificial light and developed by the same light. I was firmly convinced that this process had a great future. Unfortunately, the public did not think so at all. In fact, it was very disappointing to notice how every photographer, amateur or professional, was wedded to the older processes and wanted to have nothing to do with the method about which I felt so enthusiastic.

To make matters worse, my very best friends did not hesitate to tell me that there was no chance whatsoever for this new method of printing, because they thought that it was so much simpler and easier to print in the sun, to which everybody was accustomed. I never was more impressed with the fact of how routine holds sway over this world; but I was rather stubborn in my point of view. I kept on trying to convince others how much simpler it is to be independent of sunshine. I shall never forget the endless correspondence I had with many people all over the country. I remember too well the kind of letters I used to receive and of which the following are some examples:

"I have tried every photographic paper in existence and I have been more or less successful with all of them until I tried yours, but it is hopelessly no good. You cannot blame my insuccess on faulty manipulation, because I am professor of chemistry at ——— College."

Or another: "I am a professional photographer of twenty-five years' experience. Your paper is the greatest photographic swindle of the age. You claim your method of printing is several hundred times faster than albumen paper, and here I have kept a print in the printing frame for several hours in the sun and I can hardly see a faint image."

It was only later on that I realized that most of those people *knew too much* about photography and, on this account, never gave themselves the trouble of even glancing at the printed directions which were sent to them; they were, like so many other people, past the age where they are willing to learn anything new.

Finally, our success came from the most unexpected quarters. A new generation of modestly beginning amateur photographers came up and began to give themselves the trouble of reading and following our printed directions. To the disgust of their more experienced friends, "who know it all," they began to show them excellent prints made on the new paper, better in several respects than experienced men in the profession had been able to produce with older processes. Nevertheless, it took considerable time before so many converts had taken up the new process that the grumblers and fault-finders were finally in the minority; it required four years of strenuous introduction before the business began to show some slight profit, notwithstanding the fact that all unnecessary expenses were carefully avoided. Two years more and the business enterprise began to prosper rapidly and then I was offered good cash for my interest in the business by the Eastman Kodak Company and I retired entirely from this field.

I should mention right here that if I had tried to sell

my processes at the beginning before they had been developed into a commercial paying enterprise, I could hardly have expected anything, because at that state my inventions would have been of little or no value beyond a mere gamble. It required the careful nursing of a business enterprise, and it was indispensable to establish firmly the process on a practical commercial scale before we were in a position to dictate our own price; even at that rate, the buyers took less risk than if they had obtained the process as a gift, before it had been worked out for several years and during several seasons. If I go into all these details it is merely as a hint to some of my friends who are apt to build castles in the air on processes which are not yet beyond their laboratory stage, and who are not willing to incur all the hard work and risk connected with their full development, and yet expect to obtain a large sum of money for their mere patent rights.

UNCERTAINTIES OF CHEMICAL PATENTS

Professor Chandler has already explained to you the underlying principles of the Velox process. I should mention that velox was never patented, except that its name is a trademark. At that time I was already aware how difficult and expensive it is to carry on patent litigation and I realized too well that we could neither afford the money nor the time connected with patent fights. So I preferred to take some chances and to keep the process secret long enough to permit us to build up a solid business by the time our competitors would have been able to devise the same methods.

Although I have had to change somewhat my views on the subject of patents, I still believe that the man who takes out a patent for chemical processes and does not have at his disposal abundant means to defend his patent-rights before the courts, is at a considerable disadvantage against unscrupulous infringers. Chemical process patents which can be followed out in secrecy can be too easily infringed with impunity because it is too difficult and expensive to establish these infringements before our courts of law.

"Product patents" for chemical substances protect somewhat better; but even there, litigation is considerably more difficult and intricate than for purely mechanical patents which are easier to understand by intelligent judges even if they have no scientific training; this important point of difference has too often been lost sight of in any proposed changes of our patent laws.

But whether you patent a chemical process or not, it appears to me of the highest importance to try it as soon as possible on a small commercial scale and thus test its essential practical details before risking too large a commercial enterprise on it.

ELECTROLYTIC SODA

I was fully imbued with these facts when, about twelve years ago, I was entrusted by my friend, Elon Huntington Hooker, with the examination of the Townsend cell. The inventor of this cell, Clinton Paul Townsend, one of the most clear-minded and careful men I have ever known, had already studied the details of his invention with a thoroughness which is rather uncommon; he furthermore, in its construction, had the benefit of the engineering experience of Elmer A. Sperry of gyroscope fame. Together they had practically tested out in the laboratory everything which seemed of importance about the design and operation of the cell. At that time there existed much skepticism as to whether a diaphragm cell for the manufacture of caustic soda and chlorine would ever rival the mercury cell, brought to such a remarkable state of perfection by that distin-

guished American inventor, Castner, a pupil of Professor Chandler.

Here, then, was a distinct advance in the art, an invention which for its commercial use required a plant costing millions of dollars. I felt it was dangerous to take any such large risk until there was an absolute certainty about the smooth working of the cell. I reasoned that we all knew *how good* the cell was under laboratory conditions where it was supervised by unusually able and skillful men, but it was just as necessary to establish *how bad* the cell would be if put under actual factory conditions where it would be operated by average labor. To investigate this was very expensive and took considerable time.

Two full-sized model cells were built and operated under varying conditions, day and night uninterruptedly for months. This gave us all an opportunity of improving details of construction. With the additional experience thus gained, we could now make more correct estimates and specifications for a full-sized plant. But even this plant was not built in full at once, but only to the extent of the smallest section which could be operated. We had thus further opportunities for detecting weak points and introducing further improvements or simplifications.

After this period, however, there was no further risk in the construction of the full-sized plant. Moreover, the experience which had been gained by the preliminary expenditure of about \$300,000, prevented blunders which might have cost several millions; through carefully planned development like this, the Hooker Electrochemical Company has to-day become one of the leading electrochemical concerns of the world.

In as far as my name has been connected with this enterprise, I take this opportunity of disclaiming any further credit for the success of its technical development, and more especially for the Townsend cell, beyond the fact that it was my good fortune to work in collaboration with a group of unusually able men. Aside from the men already mentioned, there were Albert E. Hooker, H. Willard Hooker, Clarence W. Marsh, Jasper M. Rowland, T. B. Lyster, C. N. Lansing, George W. Stone and others, all of whom did their full share in introducing a number of improvements.

I mention this example of successful team work in opposition to other instances where similar problems were entered into recklessly and where, either through impatience or through false economy, a large-sized plant was put up at an enormous cost before all doubtful details of the process had been eliminated with the result that the irregularities in manufacturing became so overwhelming and money losses became so heavy that the enterprise failed before it was possible to overcome them.

The principle "Commit your blunders on a small scale and make your profits on a large scale," should guide everybody who enters into a new chemical enterprise, even if it taxes the patience of some men who cannot conceive that one single apparently minor detail in a chemical process may upset all the good points and lead to ruin.

SYNTHETIC RESINS AND BAKELITE

When I undertook the intricate study of synthetic resins, which led to bakelite, I did not rest until I had mastered the details of the subject as far as my laboratory methods allowed me to do so. Then immediately afterwards I installed a small working unit where I could prepare the material in ton lots under various conditions, so that it could be tested right and left for practical purposes. Experience has taught me that many inventions may look very good to an inventor,

but some way or another do not suit the demands of the public. On this account, before embarking on a regular wholesale manufacture, I wanted to make absolutely sure that the new substance could be used permanently for the many different industrial purposes I had in view.

I reasoned as follows: "Here is a new material which might develop disagreeable surprises either in its process of manufacture or in its uses. Therefore, the best way is to manufacture it repeatedly on a small commercial scale for a limited number of users selected in such a way that I can watch easily the progress of their work."

As usual, I found that I had much to learn and had to change my views several times. At the beginning I had the erroneous idea that almost anybody would be able to make the new material easily, himself, and that it would simplify matters if I issued licenses on a royalty plan for the use of my patents without going myself to the trouble of any manufacturing work.

I soon found I was greatly mistaken in this, and that it would have caused no end of disappointment to teach to others chemical details which, to me, seemed rather simple, but which are easily overlooked by men who can not afford to concentrate their full attention on the subject. I concluded that a simpler way would be to sell them a partly finished product and to teach them how to use it.

But I noticed, before long, that I had to go again all through the same old experience as the introduction of *velox*. I found, to my astonishment, that people who were proficient in the manipulation of rubber, celluloid or other plastics were the least disposed to master the new methods which I tried to teach them or to appreciate their advantages. This was principally due to the fact that these methods and the properties of the new material were so different in their very essence from any of the older processes in which these people had become skilled. This rather unexpected drawback is so true that even to-day the most successful users of bakelite are just those who were not engaged in plastic before; this simply for the reason that they did not have to divorce themselves from the routine of older methods, and were willing to listen patiently to suggestions from newcomers in the field.

At the beginning I committed another mistake by trying to make the processes and the material as inexpensive as possible, using mostly the cheaper cresols, being guided by the idea that cheapness is a paramount consideration in the manufacture of plastics. It took me some time to find out that the best chances for bakelite lie where special technical effects are more important than mere cheapness, and that there is no use of wasting time and money in trying to introduce the new process in such cases where about the same results could be obtained by the older plastics. In other words, the process had to be introduced on its own merits, where, for instance, unusual strength or great resistance to heat or chemicals are essential, and not as a competitor to hard rubber, celluloid or natural resins.

The most important part of the problem we had before us was to give technical instruction to those who were willing to learn, and this technical instruction ranged from the first principles of how to use the product to all the engineering details of the equipment of their plant. It took me some time to realize that, contrary to my first intentions, it would create no end of disappointments and irregular results, and it would certainly kill the reputation of the process if every licensee were allowed to carry out, according to his own fancy, the different operations from the beginning to the end. I concluded that the best way for avoiding such a failure was to conduct the manufacture

of the raw materials to beyond the stage where chemical knowledge or too much experience is required.

At first I intended to sell the raw material unmixed with fillers, so as to let the individual user make his own molding compositions. This idea, too, had to be abandoned after I found that the proper preparation of these molding compositions in itself involved an amount of skill, knowledge and minutious care, which could hardly be expected from average workmen. Unless we followed this rule, we were exposed to clash all the time with conflicting opinions or attitudes as to what was advisable and what was not, not to mention the prejudices and petty notions of foremen or superintendents. Only after all these details had been well established and taken into consideration could I proceed to organize a complete factory, and similar establishments were started in Europe. Each of these factories was supplemented by a research laboratory and experimental department in which could be investigated the different applications of bakelite as well as the refinements in its processes of manufacture and a further general scientific study of the subject.

But even then we were soon confronted with the paradoxical situation that the greatest drawback of bakelite was its multiplicity of applications, which threatened the squandering of our efforts in too many directions at the same time. On this account, we had to adopt the policy of concentrating our attention along the lines of least resistance and to be guided somewhat by opportunities and learn when and where it was best to direct our efforts, leaving it to future opportunities for developing some of the applications which at first appeared rather attractive, but which were found to involve a disproportionate amount of attention or money for their successful introduction.

PROBLEMS CONNECTED WITH NEW CHEMICAL INVENTIONS

Most people do not realize that many new chemical enterprises present problems totally different from those connected with the running or the development of a purely mechanical industry. Indeed, some chemical processes involve factors and details which are not always easy to ascertain beforehand.

To embark upon such enterprises without testing out beforehand these factors is very much like plunging into a gambling proposition; therefore, it is better to spend the necessary money on preliminary research work and preparation, then start tentatively on a modest scale, even if it tries your patience and your pocket-book. Then after you have every right to feel sure about your proposition, there is no longer any reason for further hesitation in extending your plant to the required size.

THE IMPORTANCE OF SELECTING THE RIGHT BUSINESS ASSOCIATES

In my latter enterprise I was able not only to carry out all my preliminary work by my private resources, but I felt that, if necessary, I could run the whole commercial enterprise without the financial assistance of others. This undoubtedly put me at a great advantage, as I was not hampered by any interference with my plans. If I had looked at the narrow money side of the proposition, I might have concluded that in as far as I was practically sure of the ultimate success of this enterprise, there was no reason to divide profits by accepting financial support from others. But I had learned by former experience how very valuable it is to have the coöperation of competent men for advice or influence. Therefore, in selecting business associates for my new industry I took less in consideration any money they were willing to introduce as stockholders, than

their exceptional personal qualifications and business experience.

This point of view, on which I put great stress, is too often overlooked by chemists who start in a new enterprise where they are primarily confronted with the problem of finding the necessary funds. Frequently they make reckless connections with almost anybody who can furnish them the first money, regardless of whether they are the proper persons to help or advise or inspire them in their work, or whether they are men utterly uncongenial or who do not see in an enterprise anything but getting quickly as much cash as possible out of it, quite regardless of any other consideration.

If in the enterprises with which I have been connected I managed to get along pretty well, I can attribute it, to a large extent, to the fact that in each instance I had the good fortune of being surrounded with congenial partners or collaborators who, instead of causing friction and irritation, aroused my highest enthusiasm.

Nor do I think the grouping of business associates simply a matter of luck. It is worth some deliberation in picking out the right men. If in some instances I made a mistake, I did not hesitate to rectify it even at considerable trouble and pecuniary sacrifice. To put my opinion in a short formula, I would say: "Better do not attempt much if you have as business associates only men whom you cannot trust, or who do not trust you, or who irritate or depress you, or who are dangerous by their greed, their recklessness, their superficiality, their weak character, or their general unreliability."

CONCENTRATION OF EFFORTS

Whatever task I undertook I found it necessary to concentrate my full attention and my full enthusiasm on it, sometimes during several years in succession, until I felt I had overcome all the main difficulties connected with that line of work. During these periods of intense concentration I hardly had the time or the desire to take interest in anything else; so much did I become enwrapped in my subject that even a vacation was irksome to me, because it took me away from my favorite problem.

It was only in these periods of interval between each succeeding enterprise that I made up abundantly for all this and relaxed and was open to any other matters which might strike my fancy. Then during such intervals I lost almost entirely my interest in problems which I had successfully solved, but was ready to take up a new thing.

This explains perhaps why the different subjects with which I have been connected are so little connected among themselves, and are situated in almost opposite corners of chemistry. The very difference of the succeeding subjects contained in itself that element of novelty which fed my interest and enthusiasm. It was every time like turning a new leaf, and this prevented me from becoming too one-sided.

I should state, however, that the older I became the more cautious I was not to spend my enthusiasm on subjects which I considered unworthy of my best efforts. Several of my friends asked me, "How did you happen to strike such an interesting subject as that of the synthetic resins? I can readily answer that I did not strike it haphazardly; I looked for just such a subject for a number of years until I found it among the many lines of research which I undertook in my laboratory. More than once it has happened that at the end of years of work on some particular subject or another I had to come to the conclusion that what I had found was not worth while following up further, although it

might appear attractive enough to other chemists. So, more than once, I abruptly closed my work on some subject or another and took up another line, until finally I succeeded in finding a subject on which I could feel thoroughly enthusiastic. In this way my work became a real pleasure, regardless of whether at the end it was going to bring the results which I had expected or not.

There is no doubt that I had a decided advantage over most of my fellow chemists who cannot dispose of their time the way they please, but who are bound to certain subjects whether they like them or not. If I had remained bound to my first successful enterprise, or if I had tied myself to others in some way or another, in the desire of making money, or for other reasons, I would not have possessed, at the age of thirty-five years, that absolute freedom of my time which gave me such excellent opportunities for further study and work along more congenial lines.

DANGER OF STARTING CHEMICAL ENTERPRISES WITH INSUFFICIENT CAPITAL

A great mistake has frequently been made by chemists of starting into a new business with just enough money to get along, provided everything went well. Starting a chemical manufacturing enterprise with insufficient capital is one of the surest ways of getting caught in failure. I can say that I know of few chemical enterprises, if any, where the initial expenses were not decidedly higher than what was estimated at first.

This is usually the most critical period through which every enterprise has to pass. It happens too often that there is not enough reserve capital at hand for weathering safely through the first storms through which the newly launched ship has to navigate. It is easy enough to find all the capital when things go smoothly, but it is hard work to decide anybody to advance funds for a business enterprise which encounters troubles, except at an entirely disproportionate sacrifice. More failures in chemical enterprises have resulted from this than from almost all other causes.

PRESENT OPPORTUNITIES FOR CHEMICAL INDUSTRY IN UNITED STATES. POSSIBLE SOURCES OF FAILURE

If I have risked trying your patience by going into all these details of a rather personal nature, or by giving my opinion as to the causes of success or failure of chemical enterprises, I beg to assure you that in doing so my object lies higher than merely to pose as some kind of an example to any of you.

I want the men of this country who are desirous of joining in your chemical enterprises to realize that it is not enough to have good chemists at their disposal. I want to try to convince them that there are numerous conditions under which even the best chemists cannot possibly make a success. I would like to impress this fact upon all those who have the welfare of our nation at heart at a time when no country in the world has ever had such extraordinary opportunities for becoming foremost in all branches of chemical industry.

I ask myself: Will our present magnificent opportunities lead us to efficient development of an unprecedented advantageous position, or shall we stumble and fall through sheer blundering in the way we conduct our new chemical enterprises; will these unparalleled chances of success only result in some kind of a "flash-in-the-pan"? If we turn our present opportunities into a gigantic fiasco, then let me tell beforehand to the public at large that we should not put the whole blame on our chemists.

This country has enough able chemists, all eager to do their full share of good work. Our principal universities and engineering schools are now at least as good, for all practical purposes, as the very best European institutions of the kind. If some special branches of chemical industry as, for instance, synthetic dye manufacturing, have not attained here, in the past, the same development as in Germany, this was mostly a matter of different opportunities. On the other hand, we can point to some of our other chemical industries, where conditions were more favorable and where this country has become a leader in quantity, in quality, and in pioneership.

Shall we now strengthen our position of economic independence from foreign countries by adding new chemical industries for which heretofore there was scant inducement for the man of enterprise, alongside of much better opportunities in other directions? Shall we become what we ought to be with the abundant opportunities just now at our disposal—the greatest center of chemical enterprise of the world?

The answer to this question will depend at least as much on the kind of men who are at the business end of these new chemical enterprises as on the chemical part of the problem. In this respect I look with considerable apprehension on the future of some of the ventures which are being started now by men who are merely trying to make quick money and who, in a chemical enterprise, see only a pretext for realizing their greedy ambitions; men who look upon their chemists merely as temporary tools, ready to sacrifice their enterprise and everything connected with it as soon as they can quickly cash in their profits, instead of trying to build up a permanent establishment run along steady business lines with a good underlying financial foundation, with the purpose of insuring, for years to come, regular and lasting profits, even if they may seem more modest.

It will certainly do no harm to many of our new chemical enterprises if among their directors they have at least some chemists as well as purely business men, or bankers and lawyers. I know that such a statement will go against the belief of some of my friends who imagine that a chemist or a technical man is essentially unfit to treat a business proposition in a business-like way. If the average chemist makes a poor business man it is simply due to the fact that he seldom, if ever, has an opportunity of obtaining business experience by being allowed to participate in discussing important business propositions in the councils of the concern that employs him. I would like to ask some of our business men how they ever would have acquired business sense and business methods if they never had been allowed to learn to exercise their judgment in the handling of business problems?

It is really a sad thing to see in this and some other countries so many chemical companies where the board of directors does not comprise any chemists, except in a subordinate capacity. Why should a chemist, if he is intelligent enough to master the most intricate problems of chemistry, not be able also to learn how to exercise enough common sense and good judgment to help to discuss and devise successful business policies?

Those of the large chemical enterprises of the world, which are counted as a model in their line, have always had prominent chemists among their directors, and the policy of these enterprises has not been left entirely in the hands of a set of purely business men who remained willfully ignorant of the essential technical facts upon which their enterprise was based. I have known too many instances where serious technical difficulties were not estimated at their proper value

by ignorant directors and where serious losses, disappointments and even failure arose from that source.

Of course, it would be out of the question to expect that every director in a chemical enterprise should be a full-fledged chemist, but he ought at least, to some extent, be able to follow the difficulties, the vicissitudes and progress of the technical problems with which the enterprise is confronted. It has been my experience that intelligent business men, even if they have no technical or scientific training, can easily be made to follow with intense interest the technical questions of a chemical enterprise, provided there be among them, as fellow-directors, some chemists who can keep them informed, without going into unnecessary details, and who in doing so can speak with some authority, instead of the directors obtaining their information from subaltern employees who are often so dependent on their position that they are too timid to speak without hesitation, or to impress their views with some insistence.

OUR BANKS ILL-PREPARED FOR NEW CHEMICAL ENTERPRISES

The matter of financial support for new chemical enterprises is another subject which might be considerably improved in this country. The most successful chemical enterprises of the world have been started in a small way. At first sight this would seem an unequivocal advantage; in reality it is often a serious disadvantage from the banking standpoint. Our big banks are willing enough to back vast enterprises, but look with contempt at beginning industries. Nor have our banks the organization to enable them to investigate promptly or inexpensively the prospective merits of such small scientific enterprises.

The result is that when a chemist has a good idea he has to look for private financial backers. If he could do this directly this might be well enough, but most of the time he has to go through the intermediary of a promoter, who complicates matters considerably by interposing himself as a self-constituted middle-man, and who usually begins by diluting in advance the prospective profits of the concern, even if he does not attempt foremost to insure his own immediate benefits to the detriment of the healthy future development of the enterprise.

Before the convulsions which are now shaking Europe your ardent sympathies may lie with one or the other side of the fighting nations. But your personal likes or dislikes do not diminish the fact that Germany has set us an example in industrial preparedness and that her large banks, long ago, have mastered the art of nursing new chemical industries. Those large German banks have their staff of scientific experts, whom they freely consult about any new chemical enterprise which requests their financial support. To these scientific representatives of the bank, the chemist or inventor can talk in his own scientific language and explain clearly what he has to propose, without being barred in his appeals by the hopeless ignorance in technical or scientific matters of the bank directors, or without having to resort to the trick of playing on their imagination or hypnotize them with fairy stories and stun them with exaggerated promises.

Just imagine what it would mean here in this country for a chemist to know that he can be backed by respectable banks, in any legitimate enterprise, however small, provided he can explain to their experts, in his own way, that he has reasonable probability of success. The prestige of the bank alone would give him confidence in his work, and make him immune against the usual tactics of crushing and violent com-

petition to which his powerfully established competitors might try to subject him.

Our large American banks know how to float railroad projects, loans, real estate transactions, or to consolidate established enterprises, or issue bonds or carry out similar wholesale financial operations; but they have not yet begun to learn how to support beginning enterprises based on new scientific discoveries and which on this account can best thrive and grow to powerful maturity if allowed to be tentatively started on a small scale, provided they can reckon on adequate financial support when they need it.

THE HIGHER EDUCATIONAL EFFECT OF CHEMICAL ENTERPRISES

I would certainly not take such an intense interest in the future development of the chemical industries of this country if I looked into this matter merely from the standpoint of a so-called "prosperity" of dollars and cents. I know too well that there are easier means of making money. But I am convinced that a nation of which the prosperity is based on the development of scientific industries is bound to furnish citizens of more worthy aims than a community where people get rich by slaughtering hogs and cattle, or by speculation in the fluctuating prices of real estate, or stocks and bonds, or merchandise, or by any other occupation where gain is the exclusive purpose.

A successful industry built upon sound scientific knowledge does not mean merely dividends for its stockholders or wages for its workmen. It consists in putting in practice principles of efficiency and introducing knowledge where formerly existed ignorance, and its usual accompaniments of waste, slovenliness, misery, want, vice and sorrow. It means surrounding our life with increasing and better opportunities by using the laws of nature to the greater help of man.

Progress, in general, is very slow to grow and is still more slow to assimilate. But strange to say, our reactionary attitude has, in some cases, been cured through sheer greed. To state it brutally, science only began to make rapid progress as soon as it found applications which led to the payment of cash dividends.

Chemical and electrical companies, for instance, spend more money for research and scientific investigation than all the universities combined. The result has been that it is just those two fields of science which have shown by far the greatest development, as compared to all others. By a sort of hyperinduction, science, after helping industry, got stimulated itself by the growing exigencies of industrial enterprises.

But some of you will ask me: "Where does all this lead to; will the world at large be better for it? Are not our scientists, our chemists and engineers just those who have helped to make the present war so atrocious?" To this I can answer without hesitation, that those who are responsible for what is happening now are not the scientists themselves, even if their work has been impressed into service for means of destruction and sorrow. War is many ages older than science! Greed, iniquity, lust for power, the main inheritance of the aims and thoughts of the past, rendered respectable by a rather large share of our so-called classical literature, together with our awe for tradition, are the main influences which keep us in the cold, relentless grip of the wrong ethics of bygone ages.

Even our men of science have not been able to shake off entirely so many superstitious beliefs, so many erroneous traditions, rendered respectable through pedagogic smugness and—shall I say it—with which

the minds of the children of each succeeding generation have been mummified in prejudice of certain points of view. This accounts for the fact that the average man is still more easily swayed by elegant phrases than by scientific truths. True science, on the contrary, has no more respect for the most brilliant rhetoric of classical literature, if this latter promulgates ideals which are contrary to facts, than it has any patience with the utterances of a politician whose passion or interest makes him overlook or distort facts.

As far as the ethical side is concerned, has it ever occurred to you that, notwithstanding the fact that chemistry and electricity have enriched an enormous number of people, there are few, if any, instances where scientific men, engaged in applied science, have become as absurdly rich as some of the big money hoarders of this world? Why? Because their work is too interesting to induce them to get into a life of mere money-getting; for the chemist the financial consideration is a necessity for his existence, but that is not the chief end, as it is for those whose conception of success does not go much beyond the desire of money or power.

To him whose imagination is so rudimentary that he can perceive nothing else in the cultivation of science than dry knowledge, shrivelling up of all sentiment, I should say with Jacques Loeb (see *Yale Review*, July, 1915, "Mechanistic Science and Metaphysical Romance") that there is a sufficiently wide play for our emotions in our generous response to all that is beautiful and just and in our sympathy with all those who suffer or are treated unjustly, and that the active participation in the improvement of the masses, economically, physically, socially, intellectually and esthetically, will offer for a long time to come a sufficient outlet for all human desire for emotion. What progress the world has made, not only in physical welfare but also in the conquest of superstition and hatred, and in the formation of a correct view of life it owes directly or indirectly to exact science.

It is infinitely more costly if a mistake is made in arousing nations or social groups to hatred or fear than if a mistake is made in some special problem of physics or biology; but by an irony of fate the denunciation by society in the latter case is apt to be much more severe than in the former. This is the result of the fact that the rigid consideration of truth and the feeling of responsibility for truthfulness which exact science has established, have not yet reached the masses. And this situation will last until the influence of the metaphysical romanticist has been replaced by that of the scientist.

To you, then, and all those who are willing to build up chemical industries, let these thoughts be the guiding inspiration of your work.

My friends, chemists of America, how can I let pass an occasion like this without reminding you of what you did for me?

Twenty-seven years ago I came here as a stranger among you and now I feel so much as one of you that sometimes I wonder that there was ever a time when we did not work and play together.

When I was young and poor and unknown you never hesitated to extend to me the cordial hand of welcome, you never missed an opportunity to show me your friendliness, to help me by advice or otherwise. Much of what I have used in my work I learned from you at the meetings of our chemical societies, or in the brotherly surroundings of our Chemists' Club.

You—your friendship, your generosity, your good-natured modesty, your example, inspired me in my work. I wish I could better express my thanks.

Baltimore Meeting of the American Institute of Chemical Engineers

An account of the proceedings of the first day (Wednesday, Jan. 12) of the Baltimore meeting of the American Institute of Chemical Engineers was given in our issue of Jan. 15, page 70. The papers by Mr. H. W. Jordan, on the development of the chemical coal-products industry in this country, and by Dr. Arthur D. Little, on wood-waste utilization, which were both presented on this day, are printed in full on pages 144 and 133 of the present issue respectively.

The Barium Industry

Of the last paper of the Wednesday evening session, presented by Mr. MAXIMILIAN TOCH on "the barium industry," we herewith give a fuller account, as it also dealt in a very interesting way with broader economical problems.

A metamorphosis has come over the United States within the past eighteen months such as no one could possibly have foretold, for the manufacturing industries allied to applied chemistry have been so thoroughly upset and have undergone such tremendous changes that conditions have arisen which are unparalleled.

Ever since any one of us can remember, it has been an axiom that sulphuric acid could not be profitably shipped beyond a radius of three hundred miles. Now sulphuric acid is shipped at a cost of freight alone amounting to twice its value of two years ago, and if the condition of affairs which exists now is going to continue for another year sulphuric acid may rise to a value of from $\frac{3}{4}$ cents per pound to 8 or 9 cents per pound. I say $\frac{3}{4}$ cents a pound, knowing that contracts have been entered into in this very city of Baltimore three years ago at \$5.25 per ton, or a little over $\frac{1}{2}$ cent per pound. The great advance in the price of sulphuric acid alone is not the most unfortunate thing—the real misfortune is the fact that those of us who need it and depend upon it cannot get all we need at any price, for there isn't enough sulphuric acid made in the United States to meet the abnormal demand.

Two years ago the barium industry in the United States was unknown. True, several thousand tons of barite were imported from Germany and used on the coast of the United States for making lithopone. American barite was not used for manufacturing barium salts for the reason that the freight from Tennessee and Missouri to the Eastern coast of the United States was equal to the total cost of the barite delivered on the coast from Germany and in many instances duty paid. The prevailing price for imported barite prior to 1914 was \$5.75 per gross ton landed at tide-water duty paid. The freight from Tennessee and Missouri was between \$4 and \$5 per ton; but suddenly out of a perfectly clear sky the nations of Europe grappled each other in a death-dealing struggle, and the United States was isolated from the chemical industries of the rest of the world, and those of us who had manufactured barium salts out of foreign raw material were compelled to cast about for the American minerals or else go out of business entirely.

Mr. Toch then sketched how his firm had entered the barium industry by erecting a plant at Sweetwater, Tenn. (see page 47 of our issue of Jan. 1), and offered a strong argument for a protective tariff.

Every pioneer country—and the United States is certainly a pioneer country—demands that its laborers be paid a higher wage than is necessary in the old world's settled districts. I do not speak idly, because I have studied labor conditions in the chemical industry in many of the European States. I recall particularly the conditions as they existed in Italy before the war. The same laborer who in our factory gets \$1.75 per day, and we have a number of Italian laborers who do much of the menial work—I do not mean our factory in Tennessee, but in Long Island City, N. Y.—are the same men who get 2 lire, or 40 cents, per day in Italy. The existing conditions in the district around Rome, for instance, twenty years ago were that laborers obtained 1 lire per day and board, and the board was calculated to be not over 1 lire per day, for meat and other high priced articles of food are practically unknown there. Conditions have changed in the last twenty years until now the laborer there gets 1.50 lire and board, or 2.50 lire without board. In Germany it is just about twice this amount, and in the manufacturing districts of England about 25

per cent more than in Germany, although I am frank to say that since the war I have no knowledge of the exact wages paid, but I understand on very good information that the wages have risen very materially owing to the shortage of labor.

There is absolutely no way for compensating for these economic differences in America, excepting by means of a tariff. The question of an "anti-dumping" law might possibly work out, but it is an untried factor, and although it may have good results there is no way of telling whether it would be beneficial.

Subsidy might be another way of helping the American manufacturer, although subsidy is against the policy of the United States, and it is quite obvious that if one industry were subsidized by the United States Government by direct money grants, there probably would be a newspaper revolution, to say the least. Japan, that wonderful little country which is destined to be a wonderfully big country in time, has already both subsidized and protected her chemical industries to such an extent that eventually Japan is very likely to become an exporter of chemicals and dyes where ten years ago it practically made none.

Barite is mined in the form of natural sulphate of barium. The analysis is important. "I would rather have a barite which contains 10 per cent of harmless impurities like clay and iron than a 98 per cent barium sulphate that contains 1 per cent of fluorine and lime, for while the yield in the former composition would not be so great, the yield with an improper kind of barite would not count at all, because the lining of the furnace might be practically destroyed through the presence of noxious elements."

There are at present only four barium manufactories in the United States at the present time—one of them is manufacturing the hydrate and the peroxide in relatively large quantities. My firm has devoted its entire work to the manufacture of practically the crystalline salts, like the nitrate, chloride, some sulphate and a great deal of carbonate, and in the process which we use, sodium sulphide is a by-product, which now commands the same price as the barium salts themselves. Of course, the bottom is going to drop out of all of this if we don't get the right protection, and it will indeed be a pity if the industry will suffer.

The manufacture of the barium compounds is by no means as easy as the elementary text books indicate. One of the most difficult things that I know of—simple though it may appear on the face of it—is the manufacture of precipitated barium sulphate. The barium salts are all regarded as highly poisonous, and the probability is that they are excepting those that are insoluble, like barium sulphate; and yet pulp barium sulphate is a wonderful nutrient for micro-organisms, and I have seen most beautiful and white barium sulphate decompose and become putrid in two months, and the average fungicides or bactericides known to science have had little or no effect on them. So the chemical engineer who has had a training in bacteriology and microscopy has an advantage over the lesser trained man.

Chemists have probably regarded that there is only one barium sulphate. I now know of three various types totally different under the microscope and heterogeneous in their applications. We have long been familiar with the fact that the same chemical compounds produce very different acid salts and have totally different physical qualities, and as an example I can tell you simply that lead chromate made from potassium bichromate and lead acetate, is different in its appearance from lead chromate made from potassium bichromate and lead nitrate. The resulting chemicals are identical, but in physical aspect and in color aspect they are different. The same applies to the barium salts made of different chemicals. From time immemorial the precipitated barium sulphate of commerce has been made from barium chloride and glass makers' salt cake or neutral sodium sulphate. Since the war barium chloride has become prohibitive, and there is not enough salt cake to go around, consequently the barium sulphate made in other ways is totally different from that which we have formerly known. And so this new industry has given us new problems, costs and methods of manufacture. The scale upon which the materials are made, together with the protection which should be afforded to us by a paternal government, will in the end decide whether this industry shall live.

Business Sessions

There were two business sessions held, one on Wednesday morning, the second on Friday morning. During

the Friday session Vice-President Dr. G. W. Thompson was in the chair.

At the Friday session the result of the election of officers was announced. Dr. GEORGE D. ROSENGARTEN was re-elected president for another year, and Messrs. G. W. Thompson of Brooklyn, N. Y., A. C. Langmuir of Brooklyn, N. Y., and John M. Stillman of Stanford University, California, continue to serve as vice-presidents.

The committee on public policy offered a report in which the readiness of the American Institute of Chemical Engineers to serve the Government when its services are needed was emphasized, either in a general way or in specific matters. The report was referred to the council with power to act.

The next meeting will be held at Cleveland, Ohio, probably in the latter half of June.

One of the later meetings will be held in St. Louis, and for the St. Louis members Dr. Frerichs tendered a very cordial invitation to the Institute, and spoke eloquently of the various industrial plants which could be visited in or near St. Louis.

A technical session followed.

New Process of Bleaching

A paper by Dr. S. F. PECKHAM on "a new process of bleaching" was read in the absence of the author by the secretary, Dr. Olsen.

Some years ago someone put before Dr. Peckham the problem of bleaching flax fiber by a quick process without injury to the fiber. Some thirty years ago Charles Toppan had patented a bleaching compound of which the fixed oil of mustard and petroleum were the essential ingredients. A study of this process from all available sources led Dr. Peckham to conclude that Toppan's compound, which was originally a lubricating compound, consisted of a fixed mustard oil soap dissolved in petroleum, and that by varying the proportion his bleaching compound consisted of petroleum or its distillates dissolved in a solution of fixed mustard oil soap.

In investigating this matter further Dr. Peckham found that the different benzoles dissolve in soap solution much more readily than the petroleum distillates and that the cleansing effect on the flax fiber is marvelous. Immersion in very dilute bleaching solution produced a perfect dead white bleach and left the fiber unimpaired in strength.

This method can be successfully applied to all vegetable fiber as linen is the most difficult to bleach of all of them without injury to the fiber.

I have never seen any mention made in chemical literature that benzole and its derivatives are soluble in a solution of soap, nor did I ever hear any statement to that effect. No fixed formula can be designated as soap is soluble in water in all proportions and the stronger the solution of soap the more benzole the solution will dissolve. The formula I used was for 100 lb. of flax.

Water	50 gal.
Soap	10 lb.
Benzole	3 gal.

This was used for a heavy woven linen damask, while for ordinary light cotton, such as "gray cloth," very much less material is necessary. It need not be pure benzole, but any of the light distillates of coal tar, coke oven tar or blast furnace tar, freed from impurities by washing and proper treatment.

My invention consists of a process of bleaching by substituting for the usual lime and soda boils a single boil in a solution of soap, preferably a pure vegetable oil soap, in which is dissolved a sufficient quantity of benzole (C₆H₆) or its homologues or derivatives as found in the light distillates of coal tar and similar liquids and in light distillates of some varieties of petroleum, especially that of California as distinguished from the light distillates of paraffine petroleum. The strength of the solution in both soap and benzole would depend upon the kind and character of the ma-

terial to be bleached, light cotton fabrics requiring less than heavier cottons, and any cotton less than flax, jute or hemp.

After thorough squeezing and washing to remove the soap solution, the goods or fiber may be bleached in any known chemic, but I prefer a chemic of my own invention consisting of a solution of sodium hypochlorite, prepared by pouring together, cold, a solution of 58 per cent soda ash and a solution of calcium hypochloride, stirring the mixture and allowing it to settle. Both solutions should be prepared cold, and after mixing the solutions they should be allowed to stand at least four days or until all the available chlorine in the calcium hypochlorite shall be found in combination with the sodium and in solution. No formula can be assigned for this mixture as calcium hypochlorite varies indefinitely in strength. The quantities taken should be such that there should be a slight excess of the sodium carbonate. After a great many experiments upon this chemic I have found this method of preparation, which is very unlike any which is laid down in the books, to be the only one that will bring all the available chlorine in the calcium hypochlorite into solution as sodium hypochlorite. It is better to prepare this solution of a strength 3° to 5° Twaddle, and dilute it to such a strength that an immersion of the goods from 3 to 5 hr. will effect a bleach. After washing the bleached goods in water, they are soured, washed and calendered as usual.

By this method a complete bleach of either cotton or linen can be had in from one to two working days.

I have described a process of bleaching by which the goods or fiber are prepared for the chemic by boiling in a solution of soap in which has been dissolved a sufficient quantity of benzole or its homologues or its methylated derivatives, either separately or mixed together, as found in coal tar naphthas and similar liquids and the distillations from some petroleum as above set forth.

The soap which I have used is the cheapest that I know of on the market, as it is a by-product of the refining of cotton seed oil and is used in its crude state without further treatment.

The apparatus used is a kier with a steam jacket to which is attached an inverted condenser which returns the evaporated hydrocarbons to the kier. The process was applied on a small scale and thoroughly tested out with the most gratifying results. Of course, the goods are singed and sheared as is customary. Goods in small pieces were digested for various periods of time and the resulting goods subjected to a great variety of tests excepting the effects of time upon finished goods. It was found that if the goods were thoroughly dried after thorough washing to free them from soap the effect of the chemic was very much more satisfactory than when they were introduced into the chemic damp, directly from the squeezers. This is not surprising when very dilute solutions of chemic are used as the water remaining in the goods from the squeezers not only diluted the chemic still further but filled the pores of the goods, thus getting in the way of the chemic and preventing it from doing its work.

Lutes and Cements, and Water Purification by Ozone

A paper by Mr. S. S. SADTLER of Philadelphia on "lutes and cements for chemical purposes" was next presented. In the absence of the author it was read by the secretary, Dr. Olsen. This interesting and useful paper will be published in full in our issue of Feb. 15.

The last paper of this session was presented by Mr. POWELL, on the system of water purification by ozone employed by the Baltimore County Water Company. The system was developed by their chief engineer, Mr. Walton, and its most interesting feature is the use of aluminium electrodes and micanite tubes for the dielectric. The over-all cost of purification is below \$2 per 1000 cu. ft. of water.

Friday Evening Session and Excursions

For the evening of Friday a joint meeting with the Maryland Section of the American Chemical Society had been arranged, the program comprising a paper by Dr. G. W. THOMPSON on changes in the volume and specific gravity of linseed oil films on drying and a paper by Dr. H. E. IVES on artificial daylight. This was followed by a smoker at the Johns Hopkins Club, given by the Maryland Section of the American Chemical Society.

A very fine program of excursions had been arranged. On Wednesday afternoon two different parties were formed; one visited the Maryland Steel Company's plant at Sparrow's Point, the other the Baltimore sewage disposal plant and the ozone water purification plant.

On Thursday an all-day excursion was made to Annapolis.

On the evening of Thursday a subscription dinner was held at the Emerson Hotel. It was well attended and very enjoyable. Dr. Charles F. McKenna was a brilliant toastmaster.

On Friday afternoon three excursions were made. One party visited the Standard Fertilizer Works and the Davison Chemical Works, the latter being one of the largest sulphuric acid plants and containing much of considerable interest. Another party visited the Maryland Glass Corporation, and a third party the new buildings of Johns Hopkins University.

The chief excursion on the program for Saturday was to the Tidewater Portland Cement Company at Union Bridge, Md.

Synopsis of 1915 Mineral Production

From advance estimates of the production of ores and metals in the United States, made by the U. S. Geological Survey, we abstract the following essential data:

In the Western states alone the metal production shows an increase in value of more than \$130,000,000 over the corresponding figures for 1914; and the year's increase in output for the principal metals measured in value is more than \$250,000,000. Moreover it is not unreasonable to expect that when the full returns for all mineral products are compiled they will show that 1915 was the country's most productive year in the mining industry. The total may even reach two and one-half billion dollars.

The copper mines passed all records for previous years, the 1915 output having a value of \$236,000,000, or \$83,000,000 more than the value of the production for 1914. The statistics and estimates received place the output of blister and Lake copper at 1,365,500,000 lb. or more than 120,000,000 lb. in excess of the largest previous production and 18 per cent above last year's figures. Only twice in the history of copper mining has there been a larger increase in quantity of metal produced.

The total shipments of iron ore from the mines in the United States in 1915 are estimated to have exceeded 55,000,000 gross tons, an increase over 1914 of more than 38 per cent. Based on the same price as received in 1914 this represents an increase in total value of about \$27,645,000. The increase in pig iron is estimated at 6,500,000 tons, with a total increase in value of pig iron production of more than \$120,000,000.

The output of zinc (spelter) made from domestic ores was larger than ever before, being about 425,000 tons, worth \$120,000,000, as compared with 343,418 tons in 1914, an increase of about 82,000 tons, or nearly 25 per cent in quantity and of \$85,000,000 in value. Production was increased during the latter half of the year, as the production during the first half was at the rate of 415,000 tons annually and at the rate of 436,000 tons during the last half.

The output of refined pig lead from domestic ores was about 515,000 tons, worth about \$48,500,000, as compared with 512,794 tons in 1914, an increase of only 2500 tons in quantity but of \$8,500,000, or 20 per cent in value. The production of antimonial lead was 20,550 tons, as compared with 16,668 tons in 1914, an increase of 3882 tons or 23 per cent in quantity and an increase in value of nearly \$2,000,000.

The annual preliminary estimates on the production

of gold and silver in the United States, made jointly by the United States Geological Survey and the Bureau of the Mint, are not yet complete, but early figures based on reports from the mines indicate an increase in mine production over that of 1914 of over \$7,000,000 in gold, principally from Colorado, California, Alaska, Montana and Idaho, and an increase in mine production of silver of fully 4,000,000 ounces, chiefly from Montana, Utah and Arizona. This increase in gold production may bring 1915 up to the record year of 1909, when the gold output of this country was nearly \$100,000,000.

Quicksilver also has had its best year in 1915. The quantity increased 25 per cent over 1914, but the value of the output more than doubled owing to the much higher prices. The estimated production was 20,681, flasks of 75 lb. each, valued at the average price for the year—the highest in the last forty years—at \$1,768,225. In value, this domestic production was the highest since 1881 and in quantity the largest since 1912.

Arizona

The output of gold, silver, copper, lead and zinc at mines in Arizona in 1915 was valued at \$88,551,000, according to the United States Geological Survey, an increase of nearly 48 per cent over that of 1914, which was \$59,956,029. There was very little change in the output of gold, but there were notable increases in the other metals, especially in lead and zinc. Increased prices made a difference of nearly \$26,000,000 in copper, \$400,000 in lead, and over \$2,000,000 in zinc. The output of gold in Arizona mines increased about 1 per cent over that of 1914, which was \$4,179,155. A record production of silver was made, the output increasing from 4,377,994 oz. in 1914 to about 5,458,000 oz. in 1915, or over 24 per cent. The value of this output increased about \$2,718,000. Arizona is the leading copper-producing State of the country and had an output of nearly 450,000,000 lb. in 1915, an increase in quantity of nearly 57,000,000 lb. and in value of nearly \$26,000,000. The mine output of lead increased from 15,003,068 lb. in 1914 to about 22,272,000 lb. in 1915, an increase of over 48 per cent. The value increased from \$585,120 to \$1,033,000. The mine production of zinc, estimated as recoverable spelter, increased from 9,792,337 lb. in 1914 to about 17,729,000 lb. in 1915, an increase of 81 per cent. The unusual average price of zinc for 1915 gives a value of about \$2,524,000 to this product.

California

California mine figures for 1914 were \$20,653,496 in gold and 1,471,859 fine ounces of silver; the estimates for 1915 indicate an output of \$22,860,590 in gold and 1,974,529 oz. of silver, an increase of \$2,207,094 in gold and 502,670 fine ounces of silver. California remains the premier gold-producing State of the country. The yield for 1915 is the largest in thirty-two years and with one exception the largest in fifty-one years.

The silver output from the mines shows an estimated increase in 1915, as compared with 1914, of 502,670 oz. The estimated mine yield of copper in 1915 is 44,098,552 lb., as compared with 30,507,692 lb. in 1914, an increase for 1915 of 13,590,860 lb. The mine output of lead in 1914 was 4,251,923 lb.; in 1915 it is estimated at 6,346,319 lb., an increase for the latter year of 2,094,396 lb. The estimated zinc output of the State in 1915 is 11,443,926 lb., against 389,471 lb. in 1914, an increase for 1915 of 11,054,455 lb. This is the largest production of this metal ever made in California in one year.

Colorado

The mine output of Colorado metals for eleven months of 1915, with an estimate for December, indi-

cates a yield for the year of \$22,330,000 in gold, 7,080,000 oz. of silver, 66,664,000 lb. of lead (in terms of lead bullion and lead in leaded-zinc oxide), 7,100,000 lb. of copper, and 100,000,000 lb. of zinc (in terms of spelter and zinc in zinc oxide), with a total value of \$43,100,000, compared with \$19,883,105 in gold, 8,796,065 oz. of silver, 74,211,898 lb. of lead, 6,639,173 lb. of copper and 96,774,960 lb. of zinc, with a total value of \$33,460,126 in 1914. This shows an increase of \$2,447,000 in gold, decreases of 1,716,000 oz. of silver, and 7,550,000 lb. of lead, an increase of 306,000 lb. of copper and 3,200,000 lb. of zinc. With the increased average value of metals, except silver, the values show a decrease of \$1,380,000 for silver, an increase of \$300,000 for lead, an increase of \$340,000 for copper, and an increase of \$8,065,000 for zinc.

Idaho

The output of gold, silver, copper, lead and zinc from ores sold or treated from Idaho mines in 1915 had a total value of about \$37,780,000. This is an increase of more than 53 per cent over the production of 1914, which was valued at \$24,645,848. There was no great change in the output of gold and a slight increase in that of silver, but there were material increases in the production of copper, lead, and zinc, especially of zinc. The increase in the total value of these metals, amounting to over \$13,000,000, was due largely to the increased price of lead and zinc. The mine production of gold was nearly the same as that of 1914, valued at \$1,152,315. The production of silver increased from 12,479,516 oz. in 1914 to about 13,000,000 oz. in 1915, or more than 4 per cent. The price of silver, however, was comparatively low and the value of the output was over \$400,000 less than in 1914. The output of copper was increased from 6,445,187 lb. in 1914 to about 7,169,000 lb. in 1915. The mine output of lead, which is the main mineral product in Idaho, increased from 348,526,069 lb. in 1914 to about 377,000,000 lb. in 1915. Shipments of zinc ore and concentrate increased from 54,754 tons in 1914 to about 97,000 tons in 1915. The shipments contained about 80,000,000 lb. of recoverable spelter, valued at over \$11,000,000. On account of the unusual price for zinc in 1914, the zinc produced in the State was more valuable than the gold, silver, and copper combined.

Montana

The value of the output of gold, silver, copper, lead and zinc from Montana mines in 1915 was nearly \$87,000,000, an increase of more than 81 per cent over the total value of the same metals in 1914, which was \$47,849,747, and is the greatest annual value of metals produced in Montana. There were increases in the output of all metals, but especially of lead and zinc. Though quantities show increases, the large increase in value was even more the result of a great rise in prices. The mine output of gold was valued at nearly \$5,000,000, against \$4,117,911 in 1914, an increase of over 21 per cent. The mine output of silver increased from 12,016,460 oz. in 1914 to about 14,500,000 oz. in 1915. This output shows an increase of nearly 21 per cent and is even greater than that of 1913, which was the record up to that time. Montana's greatest asset is copper, the output of which increased from 233,229,640 lb. in 1914 to nearly 275,000,000 lb. in 1915. This was an increase of nearly 18 per cent over 1914, but the output did not reach that of 1913. The mine output of lead increased considerably—from 9,656,008 lb. in 1914 to slightly over 14,000,000 lb. in 1915. This increase of over 45 per cent was due largely to the shipment of lead concentrates and of residues resulting from zinc smelting. The mine production of zinc increased from 111,-

580,544 lb. (figured as spelter) in 1914, to 184,086,000 lb. in 1915. The spelter output represented an increase of nearly 61 per cent in quantity, but as the price of the metal increased from 6.30c. in January to 22.2c. in June there was an increase in the value of the output from \$5,690,608 in 1914 to over \$26,000,000 in 1915.

Nevada

The 1915 output of gold, silver, copper, lead and zinc from Nevada mines was approximately \$34,566,000. This represents an increase of nearly 18 per cent over the output of 1914, when metals valued at \$29,300,842 were produced. These estimates indicate a marked increase in zinc output, and increase in lead and copper yield, as compared with 1914. The copper production however was below that of 1913, when Nevada had a record output of over 90,000,000 lb. There was a slight increase in the gold production, but a decrease in silver. The production of gold was valued at about \$11,968,000, an increase of 4 per cent over the production of 1914. The silver production decreased from 15,455,491 oz. in 1914 to about 14,478,000 oz. in 1915. The mine production of copper increased from 60,986,450 lb. in 1914 to about 67,480,000 lb. in 1915, an increase of 10.6 per cent. The total value of the output, on account of the high average price in 1915, increased from \$8,111,198 to approximately \$11,708,000. The lead production increased from 12,809,655 lb. in 1914 to about 14,782,000 lb. in 1915, an increase of over 15 per cent. This output, however, is not as great as that of 1913, when over 16,000,000 lb. were produced. A great increase, nearly 62 per cent, was made in the mine output of zinc in Nevada, from 12,980,232 lb. of recoverable spelter in 1914 to over 21,000,000 lb. of the metal in 1915. As the price of the metal was abnormally high in 1915, the value of the output increased from \$661,992 to about \$2,993,000 in 1915.

New Mexico

The output of New Mexico mines for eleven months of 1915, with an estimate for December, indicates a yield of \$1,500,000 in gold, 2,032,000 oz. of silver, 3,951,000 lb. of lead, 72,000,000 lb. of copper, and 24,640,000 lb. of zinc (in terms of spelter and zinc in zinc oxide), as compared with \$1,171,696 in gold, 1,777,445 oz. of silver, 1,763,641 lb. of lead, 59,307,925 lb. of copper and 18,403,392 lb. of zinc in 1914. These preliminary figures show an increase of \$328,000 in gold, 255,000 oz. of silver, 2,186,000 lb. of lead, 12,674,000 lb. of copper, and 6,237,000 lb. of zinc. With higher values of metals, except for silver, the total value was \$18,277,000, against \$11,049,932 in 1914, an increase of \$7,226,660.

Oregon

Preliminary estimates of the output of metals from Oregon mines in 1915 show material increases over the figures of 1914 in both gold and copper, and slight decreases in yield of silver and lead. The gold yield for 1914 was \$1,591,461 and the estimate for 1915 is \$1,771,618, which is an increase of \$180,157 for 1915. The silver output for 1914 was 142,552 oz., and the estimate for 1915 is 136,033 oz., or 6519 oz. less. The yield of copper in 1914 was 39,248 lb., while the estimate for 1915 is 910,104 lb., an increase for 1915 of 870,856 lb.; and the yield of lead was 16,436 lb. in 1914, as compared with 6650 lb. in 1915, or 9786 lb. less.

South Dakota

The mine production of gold from South Dakota in 1915 was \$7,390,000, compared with \$7,333,508 in 1914, and that of silver was 193,000 oz., compared with 176,642 oz. in 1914. A nominal quantity of lead was produced. Since 1876 South Dakota has produced \$192,677,000 in gold, and 6,026,000 oz. of silver.

Utah

Mines in Utah produced gold, silver, copper, lead and zinc in 1915 amounting in value to \$55,000,000. This represents an increase over the production in 1914 of nearly 50 per cent, or \$18,000,000. There was a considerable increase in all the metals. About one-fourth more ore was mined, increasing the total from 8,544,014 tons in 1914 to about 10,725,000 tons in 1915. The mine output of gold increased over 19 per cent—from \$3,265,347 in 1914 to \$3,908,000 in 1915. The mine production of silver increased from 11,54,916 oz. in 1914 to approximately 12,724,000 oz. in 1915, the increase amounting to 14 per cent in quantity and about \$169,000 in value. The copper output from Utah mines increased from 152,034,002 lb. in 1914 to about 182,589,000 lb. in 1915, the increase amounting to more than 20 per cent in quantity and about \$11,450,000 in value. The gain was made mostly by the Utah Copper mine at Bingham, which is credited with an increase of 34,207,552 lb. over the output of 1914. The mine production of lead increased from 171,323,137 lb. in 1914 to 219,098,000 lb. in 1915, or about 28 per cent. With the advance in prices, zinc ore was offered from many sources. The mine production of zinc recoverable as spelter aggregated 22,643,000 lb., valued at about \$3,224,000. This is an increase of about 41 per cent in quantity over the output of 1914, amounting to 15,989,267 lb.

Washington

The value of the mine output of gold, silver, copper, lead and zinc in Washington decreased from \$809,767 in 1914 to approximately \$728,000 in 1915. There were increases in copper and lead, to the extent of a return to normal production. There were shipments of zinc ore, the first since 1911. The gold and silver mines, however, showed decreased output, especially in the Republic mining district. The mine production of gold, which is the most important metal of the State, decreased from \$557,173 in 1914 to about \$407,000 in 1915. The silver output decreased from 264,861 oz. in 1914 to about 220,000 oz. in 1915. The production of lead from ores sold or treated increased from 65,507 lb. in 1914 to about 230,000 lb. in 1915. The mine output of copper increased from 778,723 lb. in 1914 to about 915,000 lb. in 1915, or over 17 per cent. On account of the increased price of the metal, the value increased from \$103,571 to about \$159,000 in 1915. The production was not as great as the production of either 1913 or 1912. The zinc output was entirely from the Metaline district, Pend Oreille County, where the Lead-Zinc Company operated a 50-ton concentration mill the latter part of the year. Several hundred tons of sulphide concentrates were shipped, together with some carbonate ore.

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver

Hydrolysis of Cyanide and Value of Protective Alkali.—In the July-August, 1915, issue of the *Journal of the Chem. Met. & Min. Soc. of S. Africa*, Dr. JAMES MOIR contributes some data on this subject, showing that, roughly speaking, the addition of alkali equal to one-tenth of the cyanide causes the recovery of 90 per cent of the lost cyanide. The hydrolysis of sodium cyanide in water is due to the weakness of HCN as an acid, resulting in NaOH and HCN existing uncombined in any solution of NaCN. The table gives the quantities and percentages of HCN and NaOH for any strength of total cyanide. Hydrolysis is less in the

presence of zinc cyanide, but the author does not know how much.

TABLE I

Hydrolysis of pure NaCN into HCN and NaOH at summer temperature. (Results 10 per cent to 15 per cent lower in winter.) Y = total cyanides per cent as KCN. Z = part hydrolyzed to HCN, but calculated as KCN per cent. Z = part hydrolyzed to NaOH calculated as per cent NaOH.

		100Z		
Y	x	Y Per Cent of Whole	Z Per Cent Total KCN	
1.0	0.0077	(0.8)	0.0047	(0.5)
0.5	0.0054	(1.1)	0.0033	(0.7)
0.3	0.0042	(1.4)	0.0026	(0.9)
0.2	0.0034	(1.7)	0.0021	(1.1)
0.1	0.0024	(2.4)	0.0015	(1.5)
0.05	0.0017	(3.4)	0.00105	(2.1)
0.02	0.0011	(5.4)	0.0007	(3.3)
0.01	0.0008	(7.7)	0.0005	(4.7)
0.005	0.0005	(11)	0.00033	(6.7)
0.001	0.00024	(24)	0.00015	(15)

There is some doubt whether Clennell's process tried on pure KCN would indicate the alkalinity due to hydrolysis. Assuming that it does *not* do so, but only added alkalinity, the formula

$$x_i = \frac{Y}{27,500(W + Z)}$$

gives the HCN (calculated as KCN) in presence of "Clennell-alkalinity" of W per cent. Thus if W = 0.01 per cent NaOH and Y = 0.5 per cent KCN, Z from above table is 0.0033, total alkalinity (W + Z) = 0.0133 and $x_i = 0.0014$ per cent (about one-quarter of hydrolysis in absence of NaOH, see x above). The following table has been constructed from this formula for all common strengths of cyanide.

TABLE II

Hydrolysis in presence of extra alkali.		Amount of HCN Lost by Hydrolysis Calculated as Per Cent

Behavior of Stibnite in Oxidizing Roast.—A study of the behavior of stibnite, Sb_2S_3 , under the conditions of an oxidizing roast has been studied by H. O. HORMAN and JOHN BLATCHFORD, who communicate their results in the January *Bulletin of the American Institute of Mining Engineers*. Certain difficulties inherent in stibnite are encountered in the oxidizing roast. It has a low melting point, 540 deg. to 550 deg. C., according to various authorities; the ignition point is still lower, the mineral beginning to oxidize at 290 deg. C. if the size of grain is 0.1 mm., and at 343 deg. and 430 deg. respectively for gains from 0.1 to 0.2 mm. and 2 mm.; a mixture of Sb_2O_3 and Sb_2S_3 is fusible at 517 deg. C.; both of the latter compounds are volatile at low temperatures.

The aim of the present investigation was to study the changes undergone by stibnite when roasted at

different temperatures; the composition of the roasted product; the losses which occur. The roasting furnace used was of the electric resistance type. The following table gives a summary of observations during the experiments.

Temperature, °C.	Changes
196	Faint odor of SO_2 .
219	Litmus begins to turn pink.
281	Ore becomes dull; odor of SO_2 very distinct.
336	White ashes form on rubbing, and some Sb_2O_3 is evolved.
380	Lowest temperature at which odor of SO_2 disappears.
400	Ore becomes sticky if temperature is raised quickly.

The conclusions drawn by the authors are:

1. The ignition point of stibnite is approximately 200 deg. C., as evidenced by the odor of SO_2 evolved and its action on litmus paper.
2. There is a sharp visible formation of Sb_2O_3 at 336 deg. C. At this point white fumes are evolved.
3. The formation of Sb_2O_3 takes place slowly, probably according to the reaction:

4. It is possible to eliminate all the sulphur slightly below 400 deg. C. without a large loss of antimony.
5. Stibnite is oxidized at first to antimony trioxide which begins to change to antimony tetroxide only when all the sulphide has been decomposed.
6. The amount of tetroxide increases as the trioxide decreases, the action being more rapid as the finishing temperature is raised.
7. The loss of antimony during the roast increases with the temperature.

Determination of Antimony in Roasted Stibnite.—In a paper to be presented at the February meeting of the American Institute of Mining Engineers, W. T. HALL and JOHN BLATCHFORD describe their methods for determining the condition of the antimony as well as the total quantity present in roasted stibnite. The roasted product may contain some unoxidized Sb_2S_3 and a mixture of Sb_2O_3 and Sb_2O_4 .

Total antimony was determined as follows:

Weigh out 0.25 gram of the roasted product into a trapped flask, add 4 grams of powdered tartaric acid, 2 grams of potassium iodide and 40 c.c. of concentrated hydrochloric acid. Boil the solution gently for 5 minutes and then cool to room temperature by shaking the flask while holding it under running water. Then, very carefully discharge the iodine color by the cautious addition of 0.05-normal sodium thiosulphate solution, adding a little starch toward the last. Nearly neutralize the acid with ammonia solution, but leave the solution distinctly acid. Pour the slightly acid solution into 200 c.c. of water containing an excess of sodium bicarbonate and titrate to a permanent blue color with standard 0.1-normal iodine solution.

The determination of the unchanged antimony sulphide was accomplished by a method corresponding to that used in the determination of sulphur in steel. The sample was dissolved in concentrated hydrochloric acid, the escaping hydrogen sulphide absorbed in an ammoniacal cadmium chloride solution and the sulphur in the precipitated cadmium sulphide determined iodometrically.

Inasmuch as all the antimony present in the roasted stibnite was soluble in concentrated hydrochloric acid, the solution remaining in the evolution flask after the determination of the sulphur could be used for the determination of the trivalent antimony. The details of the procedure are as follows:

To the solution remaining in the evolution flask after the determination of the sulphur, add 4 grams of powdered tartaric acid and carefully dilute with 100 c.c. of water. Carefully add 6-normal ammonia solution until

the solution is only slightly acid and then pour the solution into a large beaker containing 5 grams of sodium bicarbonate in 200 c.c. of water. Titrate with 0.1-normal iodine solution as in the determination of the total antimony.

In computing the results, it is necessary to remember that antimony tetroxide may be regarded as antimonious antimonate:

Since antimony pentoxide changes to the tetroxide when heated above 300 deg., it is fair to assume that each atom of pentavalent antimony found in the analysis corresponds to one molecule of antimony tetroxide. Then from the total quantity of trivalent antimony found, deductions must be made for the amount of tetroxide and for the trisulphide as found by the sulphur determination, the balance is the trivalent antimony corresponding to the quantity of antimony trioxide present.

Recent Chemical and Metallurgical Patents

Silver-Palladium Alloy, Substitute for Platinum.—An alloy for use in contact and spark devices to replace platinum is patented by Mr. PAUL R. HEYL of New Rochelle, N. Y. (assigned to Commercial Research Company of New York City). This alloy consists of silver and palladium in varying proportions according to the conditions under which it is to be used. An alloy of silver with 2 per cent of palladium has been found to give satisfactory results under many circumstances. When the contacts or spark points are exposed to sul-

FIG. 1—SILVER-PALLADIUM SERIES

phur compounds 5 per cent or more of palladium should be used. The alloy which was found to give the greatest resistance to spark erosion was that of 60 per cent palladium and 40 per cent silver. Palladium has a higher melting point and lower thermal conductivity than silver, consequently additions of palladium to silver raise the melting point and lower the thermal conductivity. It has been found that, on account of the high thermal conductivity of silver, the heat from the spark will be conducted away fast enough to prevent melting of the silver. In view of this fact silver-palladium alloys with very high percentages of silver can be used in a great many cases. A diagram of the silver-palladium series is shown in Fig. 1. Curve B is the melting point curve, A is the thermal conductivity curve, and curve C (shown dotted) was constructed to illustrate the resistance to spark erosion, although this may vary under different conditions. The maximum resistance to spark erosion is seen to be at substantially 60 per cent of palladium and 40 per cent of silver. Different desirable degrees of softness may be obtained with these alloys (1,166,129, Dec. 28, 1915).

Iron Alloy.—An alloy possessing properties which will permit of its being used to produce cast chilled rolls

and sand rolls that possess an extremely hard surface and strong central portion is patented by HERBERT E. FIELD and FRED. C. T. DANIELS of Wheeling, W. Va. The chilled surface of rolls made of this alloy is claimed to be so hard that it cannot be machine finished, but must be finished by grinding machines, and the central portion will withstand shocks and strains even when heated in the hot working of iron and steel. The composition of the alloy is as follows: silicon, 0.250 to 1.50 per cent; sulphur, 0.025 to 0.20 per cent; phosphorus, 0.010 to 1.00 per cent; manganese, 1.50 to 3.50 per cent; carbon, 1.50 to 3.50 per cent, and iron to make 100 per cent. The alloy may also contain small quantities of other elements, such as vanadium, titanium, tungsten, copper, or cobalt. The alloy is made in the usual way (1,166,342, Dec. 28, 1915).

Cathode Starting Sheets.—In producing cathode starting sheets as in electrolytic copper refining it has been customary to make a scratch groove on both surfaces of the blank and at a short distance from the edges. This groove is made of sufficient depth to permit a skilled operator to detach the deposited starting sheet along the groove. The undetached metal between the grooves and the outside edges has to be scrapped and remelted. Considerable time is also required to remove these edge strips. Making a scratch groove on the edge did not obviate these difficulties as the metal bridged over the groove to such a degree as to firmly unite the deposits on the opposite sides of the blank. In order to do away with the expense of remelting the scrap, and also to provide an easily detachable starting sheet, a new method is patented by EDMOND A. GUGGENHEIM of New York. In this method an insulating material is placed in a recess all around the outer edges of the blank so as to prevent metal from depositing on this insulated section. The lower edge may or may not be insulated, but it is grooved in any case. Some of the insulating materials mentioned are asphaltum, asphaltum mastic and chattron compound. The methods of insulating the side and bottom edges and of grooving the bottom edge are shown in Fig. 2 (1,163,337, Dec. 7, 1915).

FIG. 2—CROSS-SECTION OF SHEETS

Electrolysis of Zinc Solutions.—Addition of calcium carbonate to zinc chloride or zinc sulphate solutions is claimed to aid in the deposition of commercial metallic zinc, according to a patent of CLARENCE A. HALL of Mount Airy, Pa. The process does not require any marked departure from ordinary practice as to current density, and diaphragms are not necessary. Finely divided calcium carbonate in quantity sufficient to unite with the liberated sulphate or chlorine ions is added to the bath and kept in a suspended condition by agitating. It is claimed that this addition will prevent the deposition of mossy zinc (1,163,911, Dec. 14, 1915).

Electric Furnace for Melting and Heat Treating.—An electric furnace designed to reduce heat losses through radiation to the furnace walls is patented by JAMES M. LOHR and HORACE W. GILLET of Ithaca, N. Y. Several different styles of this furnace are mentioned, all embodying the same idea of subdividing the furnace into several compartments and using as heating elements the dividing partitions. Some of the styles described are a long, narrow furnace, a triangular-shaped furnace, and a furnace in the shape of an an-

nular ring. By dividing these furnaces into several compartments and using the dividing partitions as heating elements, the direct radiations from both sides of these elements will strike the crucible placed in the compartments, whereas in the old form of furnace one side of the heating element usually radiated heat directly to the furnace wall. The use of the idea has been generously thrown open to the public by the patentees (1,162,178, Nov. 30, 1915).

Reverberatory Smelting Furnace.—In Fig. 3 we illustrate a method of fettling reverberatory furnaces from hoppers placed along the sides of the furnace, patented by GEORGE C. CARSON of Denver, Colo. The

FIG. 3—REVERBERATORY FURNACE

object of the invention is to improve the former method of protecting the side walls of the furnace by hand-fettling or claying. According to the present invention, it is proposed to feed refractory material to the side walls by gravity from hoppers which are placed above the furnace and which have communication with the interior. (1,149,495, Aug. 10, 1915.)

Roasting Furnace.—A furnace structure patented by UTLEY WEDGE of Ardmore, Pa., is shown in elevation in Fig. 4. It has fixed annular walls 1 and 2, between which is a furnace chamber 3. Within the chamber is a series of superposed annular hearths, some of which, as at 4, are stationary and project from the walls, while others, as at 5, are rotatably mounted on

FIG. 4—ROASTING FURNACE

a structure 6 in the center of the roasting chamber. This structure is connected to the arms of a spider 7, which turns about an axis concentric with the annular structure of the furnace. The hearths have rabbles on their under sides for stirring and moving the ore on the hearth beneath. The annular structure 6 is composed of sections each provided with a pair of trucks 8 and wheels 9 which run on the track 10, and thus support the structure. Rotation of the spider is accomplished by power from a motor 15, communicated by a train of gearing and shaft 14 to drive chains 12, which turn the wheels 10. (1,159,141, Nov. 2, 1915.)

Method of Cooling Roasted Ore.—For the purpose of cooling the product of a prerosting furnace of the Godfrey type, which product is to be further treated by sinter-roasting, WILLIAM H. HUBBARD, JR., of Salida, Colo., has devised and patented apparatus which avoids the annoyance of dust and smoke and brings the ore into good physical condition for handling and further treatment. It consists of a circular table onto which

the hot ore is delivered and rabbled. The table may be rotatable and the rabbles stationary, or vice versa. (1,149,264, Aug. 10, 1915.)

A Novel Cooler

Though the roasting of ore, cement clinker, etc., has received the closest attention and study, the after-cooling of hot, and oftentimes semi-molten, material has generally been left to the crudest of devices. Instead of special and ample space being reserved, the cooler is fitted as an afterthought into some corner or pit, and its design also receives slight attention. Imperfect cooling, followed by rapid vulcanizing of conveyor and elevator belts and injury to chemical solutions, inevitably takes place, not to speak of the power, repair parts, cooling water, grease, etc., wasted on a machine avoided by the attendants on account of poor location, dust and heat.

Recognizing this difficulty, the engineers of one of the largest users of roasters in the world, by experiment and investigation, systematically undertook its solution. The evolution of the "Baker" cooler, patented by Mr. F. D. Baker, chief engineer of the American Smelting & Refining Company, and illustrated above, is the direct result of this work.

Red-hot material is fed continuously through a cast-iron or steel spout into one of the cone-shaped ends of a steel cylinder. This cylinder is partly submerged in a bath of water contained in a concrete, rectangular tank. The amount of submergence is adjustable, and is carefully calculated so that the weight, not only of the cylinder, but also of its load of cooling material, floats on the water by displacement. Friction, and consequently power, is therefore reduced to a minimum, and end bearings are used only as guides and to prevent the cylinder rising in case the load is reduced.

The cylinder revolves very slowly and the hot material is advanced by means of plows. The heat is transmitted to the steel shell, which is an excellent conductor. Part of it immediately passes into the water-bath, but most effective absorption takes place on that part of the shell above the bath during the evaporation of its covering of water. In proportion to the total circumference the portion of the shell in contact with the hot material at any one time is small, therefore damage to the shell by overheating is impossible, as even during a shutdown it is water-jacketed.

Discharge is effected by means of a spiral which raises the cooled material to practically the same level

as it enters the cylinder, thereby conserving head room.

The final temperature is regulated by the rate of feed, by the peripheral speed of the cylinder, and by the angle and number of plow-blades.

Though originally designed for the cooling of roasted ores, the Baker cooler has been most successfully applied to the cooling of bauxite, soda-ash and other industrial materials. It is manufactured by the Stearns-Roger Mfg. Co. of Denver, Col.

American Made Laboratory Glassware

A borosilicate glass, called pyrex, which was developed by the Corning Glass Works has proved itself equal to all demands made upon laboratory glassware. This glass possesses a very low coefficient of expansion (0.0000032) and great resistance to sudden temperature

HIGH-TEMPERATURE EXPERIMENTAL FURNACE

changes. Tests made on this glass show it to be less soluble in water and acids than the best glass heretofore made and about equally soluble in alkalies. On account of the low coefficient of expansion it has been possible to make the glassware with thicker walls than usual, thus adding to the mechanical strength. This glassware is handled in the east by Eimer & Amend in New York City and Arthur H. Thomas Co., Philadelphia, Pa.

Experimental Electric Furnace for High Temperatures

An electric furnace which was designed primarily for determining the fusion point of coal ash, metals and alloys, but which has also found application in other experimental work is shown in section in the accompanying illustration. This furnace is known as the "High Temp" furnace and is sold by Eimer & Amend, New York City.

Under normal heats the furnace reaches 1600 deg. C. in about one hour and has a maximum temperature limit of 1800 deg. C. Referring to the illustration, Z represents the heating zone formed by two concentric cylinders A and B inside, and C outside the zone. A special granular resistor material is used which is placed in the chambers R, Z and V. The portions R and V have large area and lower resistance than V, consequently the heat is concentrated in the zone Z.

Graphite electrodes are shown at L and T. These form contact with the granular resistor material. The resistor material is gradually replaced as it is used up.

COOLER

A demonstration of one of these furnaces was made at the National Exposition of Chemical Industries held last September in New York. A furnace was run continuously for a week on one charge of granular resistor material.

The furnace operates on either alternating or direct current up to 125 volts and the size of heating chamber is $2\frac{1}{4}$ in. diameter and $3\frac{3}{4}$ in. deep. All refractory parts are replaceable.

A Special Cut-Out

In localities where the atmosphere is highly charged with impurities much inconvenience and expense has always been experienced on account of the ordinary porcelain cut-outs protecting pole-type transformers blowing unexpectedly for no apparent reason. Investigation has shown that the porcelain type of cut-out cannot be prevented from absorbing a certain amount

former banks supplying by-product plants, steel mills, furnaces, etc., where the deleterious influences are particularly severe, with entire success. The S & H oil immersed cut-out is similar in principle to the high-capacity cut-out of this firm, with the addition that the whole unit is completely immersed in oil contained in a non-corroding metallic case. The cut-out has a rating of 250 amp. at 2400 volts, which is capable of handling the largest distributing transformer yet built. This cut-out is absolutely immune from the chemical influences in the air in the open or underground, and gives reliable protection with the maximum of simplicity and the minimum of expense in first cost and upkeep. It has the reliability and ruggedness of the circuit breaker at a fraction of the price.

Fifth Annual Report, Director of the Bureau of Mines

The report of the Director of the United States Bureau of Mines for the fiscal year ended June 30, 1915, contains a résumé of the work of the several departments of the bureau and sets forth the needs for the extension of the work.

In the division of mineral technology the principal investigations have related to the treatment of ores containing uranium, vanadium and radium, tungsten, platinum, thorium and mesothorium, molybdenum. Non-ferrous alloys received considerable attention, and the clay industry was the subject of some investigations.

The metallurgical division continued its investigations of smelter smoke and certain metallurgical processes relating to the recovery of sulphur from ores. The hydrometallurgy of gold and silver ores was carried on through co-operation with the Nevada Mine Owners' Association. The standardization of cyanide tests was begun. The treatment of low-grade complex sulphide ores was investigated in conjunction with the University of Utah. The smelting of titaniferous iron ores was the subject of investigation at Port Henry, N. Y. The zinc and lead ores of Kansas, Missouri, Illinois and Wisconsin were studied with special reference to losses in milling and smelting.

In the petroleum division the principal work was done on the cracking of petroleum and the conservation of natural gas.

The general research laboratory studied the methods of sampling and assaying ores and metals.

Non-Ferrous Metal Market

Jan. 26.—Price changes have been small during the last two weeks, but for the most part have shown an advancing tendency; in fact, practically all of the metals have advanced since our last report. Producers all seem to be in a very strong position and periods of dullness have no effect whatever on the market. There are those who still think the market is resting on a false bottom, but the refusal of the producers to sell or quote early deliveries even to their best friends in some cases seems to repudiate this supposition.

Copper.—The situation in this metal is without precedent, and January and February deliveries are hard to get. The market is strong and 25 to $25\frac{1}{2}$ cents is asked for electrolytic and Lake. Buyers are scared and sellers are shy. Shipping facilities were badly tied up in New England about Jan. 17, and whether they are better now or not cannot be stated. The strike in Arizona was ended on Jan. 24, and early in February normal conditions should be resumed.

Tin.—Aside from a little excitement on Jan. 15,

CUT-OUT

of volatile matter and condensation from the air. In many cases this condensation is of a virulent nature and in short time the metallic fuse element corrodes to such an extent that its current-carrying capacity is reduced until the fuse blows far below its normal rating. The result is that one or whole installations of motors are shut down inadvertently, always at considerable inconvenience and frequently heavy expense for damaged product and reduced output. This matter has become

of such importance in some localities where atmospheric conditions are particularly unfavorable that the transformers have been housed indoors, necessitating additional cost for the building as well as the occupation of space; in other instances circuit breakers have been installed on the poles for the sole purpose of obviating the corrosion of the fuse by chemicals in the air.

For several years the Chemelectric Company, 4327 Kenmore Avenue, Chicago, have been installing their S & H oil immersed cut-out for the protection of some very large trans-

CUT-OUT

when no cable advices were received from London, the market has been somewhat dull and featureless. Prices have remained firm, however, with a slight rise in the last few days so that Straits tin is now quoted at 42.25. Imports are fairly good so far this month.

Lead.—In spite of an apparently dull market the Trust price was advanced to 6.10 on Jan. 21. This is the continuation of a steady advance started last September. It is understood that some large bids at 6.05 have been refused, and it is evident that lead is in a strong position.

Spelter.—Early deliveries have been in very good demand and the market has been strong with prices considerably higher. January, February and March deliveries are much sought for. Current prices quoted range from 19.00 to 19.30 at New York.

Other Metals.—Aluminium has remained dull with prices quoted at 53.00-55.00. Antimony has met with better demand during the last week, and American, Chinese and Japanese brands are quoted at 42.50-43.00. Platinum prices are still entirely nominal at \$88 to \$100 per ounce. Silver is quoted at 57½, a new high for the movement, and quicksilver doesn't know where to stop, being quoted at \$275 per flask.

The Iron and Steel Market

Developments in January served to differentiate the steel market movement from its predecessors. It seems certainly more than a coincidence that the three great market movements of the past dozen years met their ends at the year-end. In 1907, 1910 and 1913, years following periods of heavy buying, the mills ran chiefly on their accumulations of orders. The high points in the unfilled obligations reported by the United States Steel Corporation fell on Dec. 31 of 1906, 1909 and 1912 respectively. A reasonable explanation of the phenomenon is that perforce the market experiences a lull at the holidays and unless it has an exceptionally strong undertone it fails to recover its gait. There were no heavy price advances in 1907, 1910 or 1913, though advances had continued almost to the opening of those years.

The difference this year is that in January steel prices have risen at practically the same rate as in the three months preceding. Four of the most important groups of finished steel products, bars, plates, shapes and tubular goods, experienced two advances in January, while tin plates and wire products each experienced one advance. While black sheets did not advance there was an advance in blue annealed sheets.

Strictly new buying of steel products is in general at a greatly reduced rate. The large business transacted may be regarded as of a routine character. There is very heavy specifying against current contracts, nearly all of which are at much lower prices than now quoted. There is a fair volume of contracting for bars, plates and shapes for third quarter, representing merely the fact that mills have now opened their books, in conservative fashion, for that period. The buyers would have placed their contracts earlier if permitted. There is heavy buying of war material, the tonnage running chiefly into large rounds for shells, but this business in general represents buying for second half shipment, following contracts placed long ago for first half. The production of war material promises to be at a substantially unchanged rate.

As the mills entered the year with a very large volume of specifications, averaging throughout the industry about the equivalent of three months of full production, there is no occasion for much concern as to the ability to operate throughout the year up to the physical limits. The buyers who have furnished the specifications now in hand are, as a rule, ready to furnish additional speci-

fications faster than they can be filled. While strictly new buying is light there is always some new business coming up that will be placed irrespective of the fact that prices are relatively high.

The problem of the steel mill this year is really not one of markets or of sales, but of production and transport. Labor is scarce, despite the general wage advance of about 13 per cent effective Feb. 1, and is likely to grow scarcer, both because immigration is practically shut off and because when spring opens outdoor work will make some drain upon inside operations. The question of transportation has grown more serious. Until very recently the shipment of steel from mills was interfered with only as to destination. New England was embargoed, and little steel was accepted for shipment East for export. The mill output could, however, be shipped elsewhere. Cars have been growing scarce in the past fortnight, and a number of mills have accumulated steel awaiting shipment. In the week beginning Jan. 17 the car supply in the Connellsville coke region averaged about 50 per cent of requirements, curtailing shipments by that amount and the movement of coke in transit became less rapid, so that coke receipts at blast furnaces were greatly reduced. Many had slight accumulations, but many furnaces had to be slowed down. The more heroic operation of banking did not have to be resorted to except perhaps in rare instances, but the country's pig-iron output for the month was probably reduced several per cent. Strenuous efforts made by the railroads resulted in an almost normal supply of coke cars the following week.

The Steel Corporation directors at their meeting Jan. 25 declared a dividend of 1¼ per cent on the common stock, thus restoring the old rate. As the earnings for the December quarter were \$51,300,000, the dividend, amounting to less than \$6,400,000, absorbed less than one-fourth the earnings left after the regular charges, including preferred dividend, were met. Wall Street, however, had been in some doubt whether a dividend would be declared. Inasmuch as the major portion of the advances in the steel market have occurred since Oct. 1, the shipments during the December quarter were at relatively low prices. Excluding standard steel rails, the price of which has not changed for many years, the shipments in the December quarter may be estimated to have been invoiced at about \$12 a ton below the prices now ruling in the open market for shipment at mill convenience. As the shipments in the quarter were about 3,750,000 tons, the average profit per ton, after making an allowance from the reported earnings for profits in ore transportation, was slightly in excess of \$13. The possibilities of earnings in future are therefore astonishing. Production costs are necessarily rising from a variety of influences, one of the more important of many being the general wage advance averaging perhaps 13 per cent which is being made, and which becomes effective in most instances on Feb. 1.

Pig Iron

The pig-iron market has shown no more activity in the second half of January than in the first half. Most observers regard the quietness as phenomenal in the circumstances. The psychology of the situation seems to be that the extremely strong steel market caused pig-iron consumers to cover liberally in recent months, while at the same time it encouraged furnaces to advance prices sharply, producing a price level at which buyers hesitate to make further commitments when they are well covered for a moderate period. The total advances in pig iron from the low level of the early months of last year is between \$5 and \$6 a ton, and the profits of the best-positioned furnaces as to low-

cost operation would be extremely large if they were shipping their entire current make at the existing market prices. Any further advance in pig iron must occur through an actual and serious scarcity being developed. Evidently the buyers feel it the conservative course to take their chances with the conditions when they show signs of arising. The market has been practically stationary for a month. We quote: No. 2 foundry iron, delivered Philadelphia, \$19.75 to \$20.25; f.o.b. furnace, Buffalo, \$18 to \$18.50; delivered Cleveland, \$18.80; f.o.b. furnace, Chicago, \$18.50; f.o.b. Birmingham, \$15 to \$15.50; f.o.b. valley furnaces, 95c. higher delivered Pittsburgh: Bessemer, \$21; basic, malleable and forge, \$18 to \$18.50; No. 2 foundry, \$18.50 to \$19.

Steel

The market for soft steel billets and sheet bars is quotable at about \$32 to \$33 for Bessemer and \$35 for open-hearth, f.o.b. maker's mill, Pittsburgh or Youngstown, but the quotations are practically nominal. Regular consumers have contracts at lower prices, and while deliveries are not in all instances fully up to requirements, prices being obtained on ordinary finished steel products do not justify paying prices that would be asked on fresh transactions. Forging billets made to war specifications are bringing usually between \$50 and \$55. A sale of 4000 tons of rods for February and March shipment is reported at \$55, but the market for ordinary deliveries is quoted at \$42 to \$44, though such figures are regarded as largely nominal.

Finished Steel

About Jan. 21 plates were advanced \$3 a ton to 2.00c. and bars and shapes \$1 a ton to 1.90c. Effective Jan. 24 wire products were advanced \$2 a ton, woven wire fencing being advanced three points to 64½ per cent off list. Regular mill prices are given below, f.o.b. Pittsburgh, unless otherwise noted, and are for delivery at mill convenience, higher prices ruling for early shipment of some products, particularly bars, plates and blue annealed sheets.

Rails, standard sections, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 2.00c.

Shapes, 1.90c.

Steel bars and bands, 1.90c., base; steel hoops, 2.10c., base.

Iron bars, Philadelphia, 2.259c. to 2.359c.; Chicago, 1.75c. to 1.80c.; refined iron bars, Pittsburgh, 2.00c. to 2.10c.

Plain wire, 2.05c., base; galvanized wire, 1.75c.; wire nails, \$2.20 per keg, base; painted barb wire, 2.35c.; galvanized barb wire, 3.05c.

Sheets, blue annealed, 10-gage, 2.65c. for Bessemer, 2.75c. for open-hearth; black, 28-gage, 2.60c. for Bessemer, 2.60c. to 2.70c. for open-hearth; galvanized, 28-gage, 4.75c. to 5.00c.; painted corrugated, 28-gage, 2.80c.; galvanized corrugated, 28-gage, 4.80c. to 5.05c.

Tin plate, \$3.75 for 100-lb. cokes.

Steel pipe, ¾ to 3-in., black, 76 per cent off list; galvanized, 60½ per cent off list.

Boiler tubes (less than carloads), 3½ to 4½-in., 64 per cent off list.

Structural rivets, 2.60c.; boiler rivets, 2.70c.; cold-rolled shafting, 45 per cent off list; cold-rolled strip steel, 3.75c. to 4.00c., base.

Titanium Production in 1915.—During 1915 the American Rutile Co. produced 250 tons of rutile worth between \$25,000 and \$30,000 at its plant at Roseland, Va., according to the Geological Survey. This is the largest production to date.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Aqueous Bath Apparatus

(Continued)

512,417, Jan. 9, 1894, Charles N. Waite of Newton, Mass.

Relates to an insulated joint between sections of a metallic conduit, generally a lead pipe, for conducting chlorin gas from the anode compartment of an electrolytic cell. One end of a conduit section is enlarged to a cup-shaped receptacle for the end of another section of the conduit; within the cup-shaped receptacle and surrounding the inner pipe-end is an asbestos washer, and above the asbestos washer is poured melted Trinidad asphalt or other suitable cement not affected by chlorin.

512,970, Jan. 16, 1894, John P. Johanson of New York, N. Y.

Relates to an electric washing apparatus, which is said to aid in the cleaning of soiled clothing during the operation of washing. It consists of a pair of electrodes connected by a flexible conductor to a source of low voltage current; the electrodes are provided with insulated handles and hooks, by means of which they are hung from the edge of the ordinary metal wash-boiler in which they are suspended during the boiling of the clothes in soapy water.

522,619, July 10, 1894, Isaiah L. Roberts of Brooklyn, N. Y.

Relates to an electrolytic-decomposition tank made of iron or like metal, that may serve as the cathode. The anode consists of a carbon rod placed within a bag of pulverized anthracite coal, the coal serving as a diaphragm. The anode may when desired consist of other material than carbon, and the coal dust diaphragm may be retained by other means than by a bag. In practice, a large iron tank is used with a plurality of anodes; the tank is subdivided into small units by placing upright pieces of angle iron, so as to produce separate cells for each anode, the joints between the several angle irons being loose, thereby enabling a circulation of the electrolyte.

523,099, July 17, 1894, Clarence M. Barber of Cleveland, Ohio.

Relates to an apparatus for electroplating a large number of separate articles, such as are light carbons, and consists of an endless conveyor, such as a pair of sprocket chains connected together by parallel links or bars so as to produce a unitary conveyor. Each of the parallel connecting links carries a clamp to support an article to be electroplated, automatic means being provided to fill and empty the clamps, and to immerse and remove the articles into and from the plating vats. The patent should be consulted for details.

550,812, Dec. 3, 1895, Elbert R. Allen of Wallingford, Conn., assignor to Simpson, Hall, Miller & Co. of same place.

Relates to a holder to support spoons, forks, etc., to receive an additional deposit upon the surfaces which are subjected to the most wear. The support consists of a long horizontal clamp made of superimposed clamping bars, the support mounted at its ends upon two upright rocking arms, which enables the tilting of the article to be plated, as a spoon, which is ordinarily clamped at the center, either to one side or the other, to vary the surface immersed.

553,732, Jan. 28, 1896, James H. George of New York, N. Y.

Relates to baths or tanks for electroplating such surfaces as the sides of the hull of a ship. The bath or tank is trough-shaped, and consists of a more or less flexible material such as papier-maché. The tank has broad, flange-like, concave edges, and is held against the side of a ship by suitable shore-pieces; the air is then exhausted from the tank by an air pump which maintains the exhaustion as long as the tank is in use. Suitable electrolytes are allowed to flow into the tank after it is in place, through one or more openings controlled by valves. The patent contains a reference to U. S. patent 498,707.

556,854, March 24, 1896, John Leith of St. Helen's, England, assignor to the Electrochemical Company, Limited, of same place.

Relates to conductors for supplying current to a number of electrolytic cells, or units of current consumption. The conductor consists of a cable made of a plurality of separate insulated wires, each wire supplying the anodes of one vat or cell, a duplicate cable supplying the cathodes of each cell, there being as many separate insulated wires to a cable as there are cells or units. With a long row of cells, the diameter of the cable will diminish from the first to the last, due to the reduced number of wires in the cable as the distance increases, thereby effecting an economy in copper over the practice of using a conductor of the same diameter along the row of cells.

563,972, July 14, 1896, Rudolf Kroseberg and Eugen Straub of Berlin, Germany, assignors to said Kroseberg.

Relates to electrolytic cells in which hollow electrodes are used. The hollow electrode may constitute a cell in that it consists of an anode and a cathode secured to the sides of an annular insulating member, the latter provided with an inlet and outlet for electrolyte. Several of such complete hollow cells are placed in a larger cell containing a liquid maintained at a desired temperature, thus assuring electrolysis under desired conditions. The patent also states that a liquid of any desired temperature may be caused to circulate through the hollow cells, and electrolysis takes place in the outer larger cell.

565,953, Aug. 18, 1896, Emile Andreoli of London, England.

Relates to an apparatus in which is carried out a process of so-called indirect electrolysis. The apparatus consists of a three-compartment cell, containing two porous diaphragms. The outer compartments constitute anode and cathode compartments, the inner compartment contains the electrolyte to be subjected to the indirect electrolysis. The apparatus may be used for preparing hydrosulphite of sodium as follows: In the anode compartment is placed a caustic potash (probably caustic soda) solution, and in the negative compartment a sodium chloride solution. In the central compartment is placed a solution of bisulphite of sodium, and immersed therein, but unconnected to the electric circuit, are immersed pieces of zinc in the form of gauze, perforated sheets, etc. During the passage of the current, the indirect electrolysis reduces the sodium bisulphite to sodium hydrosulphite. The sodium bisulphite solution may continuously circulate through several such tanks, and then through a bleaching tank, then through the electric cells. The apparatus may also be used to deposit gold and silver from their solutions, in which case the pieces of metal in the central compartment may contact with a layer of mercury at the bottom to maintain an amalgamated surface.

565,975, Aug. 18, 1896, James H. George of New York, N. Y.

Relates to apparatus for electroplating the sides of

vessels, and contains a reference to U. S. patent 498,707, and to a co-pending application Serial No. 527,916. The present patent relates to a system of supply and drain pipes to circulate the electrolyte to detachable vats temporarily secured on the sides of the vessel. The pipe system constitutes a closed circulating system in which the electrolyte passes through several detachable vats, and through a tank which maintains the electrolyte at the proper strength.

Personal

Mr. D. B. W. Alexander has changed his address from the General Petroleum Co., Los Angeles, Cal., to the Barber Asphalt Paving Co., Maurer, N. J.

Mr. William Bjorkstedt has resigned his position with the electric furnace department of the Siemens & Halske Co., and has accepted the position of works manager of the Stavanger Electro-Staalverk in Stavanger, Norway.

Mr. P. A. Boeck of the Kieselguhr Company of America delivered an illustrated lecture on "High Temperature Insulation" before the Chicago Section of the American Society of Mechanical Engineers on Jan. 14.

Dr. F. G. Cottrell has been appointed chief metallurgist of the U. S. Bureau of Mines and will be located at Washington, D. C.

Dr. Saul Dushman of the General Electric Co. Research Laboratory and formerly of the Chemical Department of Toronto University, presented recently an illustrated lecture on "Electrons, Atoms and Energy Quanta," before the Niagara Falls Section of the American Electrochemical Society. This was followed by a review of the papers given in the past year, in which the entire section participated. The annual election was held at the same meeting and the same officers re-elected.

Mr. H. A. Guess has returned to New York after an extended trip to Chile, during which he visited the Braden and Chuquicamata properties.

The Colorado section of the A. I. M. E. elected the following officers at the annual meeting, Jan. 7: Chairman, L. P. Hammond; vice-chairman, F. H. Bostwick; secretary-treasurer, P. M. McHugh; directors, G. A. Kennedy and M. S. MacCarthy.

The marriage is announced of Mr. A. M. McAfee of the Gulf Refining Company, of Port Arthur, Tex., to Miss Marguerite Avelette Calfee, of Uvalde, Tex., on Jan. 11, 1916. Mr. McAfee is probably best known through his aluminum chloride process for the production of gasoline from high-boiling petroleum oils. A paper by him on this subject was published in our issue of Sept. 15, 1915.

Mr. Clarence W. Marsh, well known through his twelve years' connection with the Development & Funding Co. and the Hooker Electrochemical Co., as chief engineer and special investigator and a director, has opened offices as an independent consulting and chemical engineer at 201 Devonshire Street, Boston, Mass.

Dr. John A. Mathews, president of the Halcomb Steel Co. of Syracuse, N. Y., lectured on Jan. 14 before the Chicago Section of the American Institute of Mining Engineers on "Iron in Antiquity and To-day." The address was illustrated with numerous lantern slides made from historic cuts and illustrations from Dr. Mathews' private library, which contains many rare and old volumes, the oldest dating back to the year 1540.

Mr. Carl A. Nowak has changed his address from Manitowoc, Wis., to St. Louis, Mo., where he will be located at 207 Railway Exchange Building.

The newly elected officers of the Colorado Scientific Society are: **H. C. Parmelee**, president; **T. B. Stearns**, first vice-president; **F. E. Shepard**, second vice-president; **A. J. Hoskin**, secretary; **J. W. Richards**, treasurer; **S. A. Ionides** and **V. G. Hills**, members of the executive committee.

Mr. F. E. Pierce presented a paper on "The Zinc Smelter of To-day" before the annual meeting of the metallurgical and mining section of the Engineers' Society of Western Pennsylvania on Jan. 25.

Mr. R. E. H. Pomeroy, superintendent of the Steptoe smelter of the Nevada Cons. Copper Co., has been visiting at Anaconda and Great Falls.

Mr. John H. Rickard is superintendent of the anti-monopoly smelter near San Francisco.

Mr. J. M. Mitchell Roberts, metallurgist for the Seoul Mining Co., Korea, is on a visit in California.

Obituary

Florentine J. Machalske, an electrochemist, died at Plattsburgh, N. Y., on Jan. 16. Since November 1912 he had been experimenting with a new electric-furnace process for manufacturing steel.

B. E. Sperry, president of D. R. Sperry & Co., Batavia, Ill., died on Jan. 5, after an illness of about three weeks. He was sixty-three years of age and had been associated with his company since his eighteenth year. He filled the position of president for nearly a quarter of a century, and during that time the company's business greatly increased. He was the original inventor and designer of the well-known Sperry filter-press, the Sperry patent filter plate and the switch cock and double gutter system of filtration. Another of his inventions consists of the Sperry swing kettle vacuum pan, an ingenious and convenient type of machine found in many branches of the chemical industry. Due to his efforts a complete line of caldrons suitable for farm and industrial uses was developed. He was born in Malone, N. Y., and leaves a widow, five daughters and one son.

William Barker Ruggles, founder and president of the Ruggles-Coles Engineering Company, of New York City, died on Jan. 23 of pneumonia at the age of fifty-four years. He was born at Bath, N. Y., and a graduate of Cornell University. At the time of his death he was president of the Ruggles-Coles Engineering Company, the Novella Cement Company (Guatemala City, C. A.) and the Niagara Cement Company, and a director and the consulting engineer of the Buffalo Cement and Potash Corporation. He was the inventor of the Ruggles-Coles double-shell dryer and of many other engineering devices. He was a member of the American Society of Mechanical Engineers, Engineers' Club, Machinery Club, Cornell University Club and Psi Upsilon Club, and a trustee of Trinity Episcopal Church of Bayonne, N. J., where he had resided for twenty-four years. He had a wide circle of acquaintances among the members of the engineering profession and was highly respected as an able engineer and kind and genial man. He is survived by a widow and one daughter.

John Alexander Hill, president of the Hill Publishing Company, died suddenly from heart disease on Monday morning, Jan. 24, while traveling in his motor car from his residence in East Orange, N. J., to his place of business in New York City, at the age of 57 years. In John Hill one of the two or three great "captains of industry" in modern American technical journalism has gone into eternity—a typical American self-made man. He was an apprentice in a country

printing office at 14, a locomotive engineer on the Denver & Rio Grande at 20, founder and editor of the *Daily Press* of Pueblo, Colo., at 27. His connection with technical journalism dates from the time when as locomotive engineer he contributed stories of the railroads and "Jim Skeevers' Object Lessons" to *Locomotive Engineering*. In 1888 he was called to New York to take charge of this paper and became part owner, but sold his interest in 1896 to purchase the *American Machinist*. In 1902 he bought *Power* and organized the Hill Publishing Company, which has since acquired the *Engineering and Mining Journal*, *Engineering News* and established the *Coal Age*. Mr. Hill is credited with

THE LATE JOHN A. HILL

many achievements in the business of publishing technical journals. A fine monument to his life and work is the Hill Building at Tenth Avenue and Thirty-sixth Street, New York, the home of his papers. Completed in 1914, it is a magnificent structure, equipped with all imaginable mechanical devices—many of his own design—to expedite work and safeguard employees. His ideal of a printing plant was that it should be as dainty and as cleanly as any business office. Accordingly the linotype machines are enameled in white and the composing rooms, the entire engine-room fixtures and the frames of the great presses and binding machines have a similar enamel finish. His life and work has left permanent marks on technical journalism. He was a genial man, fond of companionship and loyal to his friends and to every one of his employees. They placed a tablet to him in his new building still in his lifetime. It reads: "Within this monument to independent truth and service in engineering journalism the employees of the Hill Publishing Company have placed this tablet—an appreciation of the man and employer, John A. Hill."

Industrial Notes

New Utah Acid Plant.—A new sulphuric acid plant to make 100 tons of acid per day is contemplated by the American Smelting & Refining Co. The exact site has not yet been decided upon, but it will likely be somewhere in the Salt Lake Valley.

The Southern Electrochemical Co. will begin operations shortly at its plant in Great Falls, S. C. Nitric acid will be produced from the air by the Pauling process. Power will be derived from the Catawba River. The present output will be about 4 tons of acid per day.

The New Castle Rubber Company, New Castle, Pa., will increase its capital stock from \$500,000 to \$1,000,000 by a vote of the stockholders. Large additions to the plant will be made.

Benzol and Toluol Production.—Production estimates in this new American industry should prove interesting. According to returns to the Geological Survey, the indicated production was 13,942,763 gal. in connection with which there was produced 761,256 lb. of naphthalene. By the end of 1915 there were nineteen new plants in operation recovering benzol and others in the course of erection. Before the war there was but one plant in operation. Some of the plants are not equipped to separate the different oils in the crude, and over 7,000,000 gal. was reported as crude and was shipped to refineries. In the 6,620,093 gal. refined at the place of recovery, there were 4,833,939 gal. of 100 per cent benzol, 1,315,727 gal. of toluol and 470,425 gal. of solvent naphtha. Thirty-one coke-making establishments, with 4993 by-product ovens, contributed to this total, and it is estimated that between 8,000,000 and 9,000,000 tons of coal was carbonized in the ovens. The annual capacity of the benzol-recovery plants now in operation is estimated at over 20,000,000 gal., and with new plants being constructed it will probably reach 22,000,000 gal. This enormous production is much greater than the normal consumption, but it is possible that new uses may be found for it after the war.

Tungsten Production in 1915.—Preliminary returns to the Geological Survey indicate that the production of tungsten ores in 1915 broke the record and that about 2165 tons of concentrates, carrying 60 per cent WO_3 , was produced. This had a value of about \$2,000,000. The largest previous output was in 1910, when 1821 tons was produced. The price in the early part of 1915 went as low as \$5.80 per unit. In the fall unheard prices were reached and up to \$50 and higher per unit was paid for tungsten concentrates. Prospecting did not follow at once as the prices moved so rapidly, but early in the fall considerable prospecting was in progress. Mills were erected by the Primos Chemical Co. at Dragoon and by the National Tungsten Co. at Arivaca, Ariz., to treat the tungsten ores.

Antimony Production in 1915.—According to preliminary figures collected for the Geological Survey, the production of antimony ores in the United States is estimated to have been about 5000 tons, containing 2000 tons of antimony valued at \$325,000. Practically all operations of the past year were new, most were small, and they were widely scattered, so it is difficult to obtain exact figures so soon after the close of the year.

New Uses of Monel Metal.—In our Jan. 15 issue, page 110, in the article under this title mention was made and an illustration shown of a large valve for superheated steam service weighing 3500 lb. made by the Nelson Valve Co., Philadelphia, Pa. This was stated to be a Monel metal valve, but in order to correct any misconception, it should be stated that it is a cast-steel valve, the body having cast Monel seat rings and the bonnet a Monel "pack-when-open" bushing. The valve is of solid wedge type, the wedge being cast in one piece of Monel metal and the stem also made of Monel metal.

The American Blower Co., Detroit, Mich., has sent us its latest edition of Sirocco Service, the little pamphlet devoted to blowers. This pamphlet describes various uses for Sirocco blowers.

The Anaconda Copper Mining Co. has placed an order for six more 10-ft. diameter by 4-ft. cylindrical length Hardinge ball-pebble mills making a total of fifty-six conical mills for its new plant. The Hardinge company reports that the ten mills are direct connected herringbone-gear driven, operating with 75 per cent less power than originally estimated.

At the annual meeting of the stockholders of the American Metal Products Company, Milwaukee, Wis.,

makers of Ampeco bronze, the old board of directors was re-elected as follows: Peter J. Weber, president; Henry E. Berlie, vice-president; Wm. J. Eberle, secretary and treasurer; Richard Gaertner, manager, and Charles E. Helm and August Littmann. Action was taken to secure a larger plant for the increased business of the company.

The Bailey Meter Company has been incorporated under the laws of Massachusetts for the manufacture of recording meters and instruments for power plants and general use. The new company will be in charge of Mr. E. G. Bailey, and will be located at 141 Milk Street, Boston.

Cyanamid Works.—At the end of Mr. W. S. Landis' paper in our issue of Jan. 15 (pages 87 to 90) the place of the American Cyanamid Company was given as Niagara Falls, N. Y., which should read Niagara Falls, Ont., where the company's manufacturing plant is located. The general offices are at 200 Fifth Avenue, New York City, and division sales offices are maintained at Atlanta, Ga., and San Francisco, Cal.

Adjustable-Pressure Centrifugal Pump.—A centrifugal pump has recently been placed on the market by the Karl Kiefer Machine Co., Cincinnati, Ohio, which has a pressure adjusting arrangement by which any pressure may be secured from practically nothing up to 35 lb., depending on the size of the pump. It is intended to be used especially with filters or filling machines where the adjustable pressure is a desirable feature.

The Miller Smelting & Refining Co., Cleveland, Ohio, assayer, smelter and refiner of gold, silver and platinum, announces that it is now located in the Ellastone Building, East Fourth Street and Prospect Avenue. Its old location at 612 Euclid Avenue was burned out.

The Palo Company, New York City, announces its entrance into the laboratory supply and assayer's material business, with headquarters at 90-94 Maiden Lane. It has issued a catalog describing biological, bacteriological, chemical, physical, metallurgical, optical and astronomical apparatus.

The Quigley Furnace & Foundry Co., Springfield, Mass., has awarded a contract for the construction of a new foundry building, 91 x 208 ft.

The Richardson Scale Company, Passaic, N. J., has issued a beautiful illustrated catalog describing its automatic weighing equipment, including the Merrick conveyor weightometers.

The Sarco Company, Inc., has recently been formed by the Sarco Engineering Co. and the Roller-Smith Co. The new company will handle all sales of the Sarco steam traps and temperature regulators, with offices at South Ferry Building, New York City.

Decks for Round-Tables.—In the construction of cement decks for round-tables used in concentrating slime, it has been proposed to mix oil with the cement. A further suggestion is to mix with the cement oxidized linseed oil, after it has been dried and ground according to practice in making linoleum. In the latter industry, boiled linseed oil is allowed to flow in successive layers over vertical sheets of cotton "scrim," each layer being allowed to harden before the next flows on. When a "skin" of $\frac{1}{2}$ -in. thickness is thus formed, the mass is ground for incorporation with resin, kauri gum and ground cork to form linoleum. The addition of linseed oil thus prepared to cement for use on a table deck might improve the surface for collecting and holding mineral.

Magnesite from Greece.—Magnesite may be obtained from Greece without difficulty, according to Commerce Reports, published by the Bureau of Foreign and Domestic Commerce, Washington, D. C.

New York Meeting of the American Institute of Mining Engineers

For the past few years the meetings of the American Institute of Mining Engineers have formed a string of grand successes—Great Falls and Butte, Salt Lake City, San Francisco—and in September there will be the Arizona meeting. But in the present week New York City has the privilege of welcoming the mining men from near and far. The outlook for a very profitable and enjoyable meeting is excellent. New York will spare no effort to make its visitors feel at home—and they will find that at present with the new subways in the making, the metropolis at the Hudson is in places nothing more than just a big mining town.

Our Noteworthy Pig Iron Production

The United States is now making more than one-half the world's pig-iron production. While pig-iron production outside the United States is less than before the war, the production of the United States is at a rate 25 per cent greater than the average rate in the record calendar year, 1913. Production of pig iron in the United States compares with the world's production as follows, the figures representing gross tons of 2240 pounds:

	United States	World	United States, Percentage
1850.....	563,755	4,400,000	12.8
1890.....	9,202,703	27,000,000	34.1
1900.....	13,789,242	40,200,000	34.3
1905.....	22,992,380	54,000,000	42.6
1910.....	27,302,567	65,300,000	41.7
1911.....	28,649,547	63,300,000	37.3
1912.....	29,726,937	72,600,000	41.0
1913.....	30,966,152	78,000,000	39.7
1914.....	23,322,244	60,000,000	38.9
1915.....	29,906,000	60,000,000	49.8

The above figures illustrate quite a story. From 1850 to 1890 there was what then appeared to be a tremendous growth in the iron industry, and the United States, then a very new country, naturally witnessed the greatest growth within its own borders. In the decade following there was no lack of either energy or brains in the United States, for there was noteworthy technical progress, but during the major portion of the decade there was an industrial depression in the United States, which prevented the country from doing more than maintaining its proportion of the world's production. Then there began a race between the United States and Germany, the honors going to the United States for several years, but Germany afterwards expanding more rapidly in production, whereby the percentage of the United States was sensibly reduced. The production of the United States in 1913 was very large, but not sufficient to result in as high a percentage as had been reached in 1910 or 1912. The year 1914 comprised seven months of peace and five months of war. The output of the

United States was low throughout the year, from industrial conditions, while the output of the European countries was greatly reduced in the early months of the war, the net result being that production in the United States, while greatly reduced, comprised almost 40 per cent of the world's production, which was so much the worse for the showing the rest of the world made. The proportion of the United States in the first seven months of 1914 was much less than 40 per cent. In 1915 the world outside the United States recovered part of the ground lost, producing iron at a rate considerably in excess of the rate in the early months of the war, but still far below the rate obtaining before the war. The production of the United States in 1915, although 3.5 per cent less than that in the record calendar year, nevertheless comprised practically one-half the world's production, against 43.4 per cent (not shown in the above table) in 1906, the highest proportion previously attained by the United States.

At the present time the United States is still farther in the lead, with production at the rate of 39,000,000 tons. The present rate of production outside the United States cannot be precisely estimated, but it is certainly very much less than 39,000,000 tons. It may not be at much more than 30,000,000 tons, the average rate in 1915, but taking it at 33,000,000 tons, which seems to be rather a high estimate, the proportion of the United States would be 54 per cent, a proportion which nothing but the war, probably, could have brought about. It seems improbable that either during the war or for years afterwards the United States can make a larger proportion of the world's pig iron than it is making at the present moment.

Smelting Bolivian Tin in the United States

The Smelting and electrolytic refining of Bolivian tin ore by the American Smelting & Refining Company at Perth Amboy, N. J., will remove "one of the most remarkable incongruities in the commercial relations of the United States and South America," to quote the Minister from Bolivia to the United States. Bolivia is one of the few countries in the Western Hemisphere that produces tin ore in large quantities. The United States, on the other hand, is the largest consumer of tin in the Western Hemisphere, importing annually from 45,000 to 50,000 tons but producing a negligible quantity. Nevertheless Bolivian tin ore has hitherto gone first to England or Germany for smelting and refining, and then brought to the United States, the latter country paying the cost of European production and transportation. This anomalous condition will now be changed; for the American Smelting & Refining Company has contracted for the delivery of 750 tons of high-grade Bolivian tin ore per month to be smelted at Perth Amboy, and the new plant will gradually be brought to its capacity of 1200 tons per month. The electrolytically refined product will be equal in quality to the best Straits tin.

The economic importance to this country of this change is only realized by a study of the value of Boliv-

ian imports and exports and the small part which the United States has previously played in this business. According to the Department of Commerce, Bolivian imports in 1912 were valued at nearly \$20,000,000, of which the United States supplied only \$1,787,321 worth, as against \$6,423,802 for Germany and \$3,528,041 for the United Kingdom. In the same year the latter nation bought over \$26,000,000 worth of Bolivian exports, while the United States was a buyer to the extent of only \$152,582, or less than one-half of one per cent of the total. With the establishment of a tin smelting industry in this country Bolivia will have a local credit of millions of dollars per annum, and it must inevitably follow that our products will flow to Bolivia in greatly increased quantities.

The Bolivian tin industry was in unsatisfactory condition following the outbreak of war in Europe. Exports fell off and prices declined. The Bolivian government, therefore, welcomes the opportunity for closer commercial relations created by our purchase of one of her principal mineral products. Commercial treaty relations are satisfactory, and no unfavorable tariff is to be adopted by Bolivia that would affect the export of tin to this country. On the whole, the establishment of this tin industry promises to be an entering wedge for wider commercial relations with South America that should be of lasting benefit.

The Chemist and the Banker

In Dr. Baekeland's Perkin Medal address published in our last issue he put forward as an axiom: "Commit your blunders on a small scale and make your successes on a large scale." He then brought out the mental unpreparedness of American bankers to embark in chemical enterprises by the only wholesome and reasonable method of beginning small and growing large, to accord with this maxim.

The reason for this is that our bankers do not know enough chemists and our chemists do not know enough bankers. Of course, the banker is unwilling to risk good money on an experimental lay-out to test some chemical theory that "nobody" can understand. One might as well ask the chemist to invest his savings in cases of hosiery that are said to be a great bargain. He doesn't know the hosiery market and he would be afraid to take the stuff as a gift—and pay storage charges on it. And to any chemical proposition the banker is likely to say: "I don't know anything about chemistry," while his acquaintance with the family doctor is close enough to persuade him that he does know something about medicine and surgery.

Chemists and bankers do not know each other for a social reason. They have not been generally introduced, and when they have met they have not had things to say to one another that were interesting. Now there is no source of information too humble to be worthy the attention of him who seeks knowledge, and in this connection it might do no harm to observe the arts of the social climber who desires to break into society when she moves to town. She may be a very

vapid person, and exceedingly foolish, but she must use her wits to succeed. We have, in this example, the phenomenon of a human animal employing its wits to accomplish the fulfillment of its desires, which is always an interesting one. She lays her plans and makes her arrangements so that, to all appearances by accident, she is introduced to the most influential woman, to the dominant dowager of the temple of fashion. For this occasion she has prepared herself and trained like an athlete. By word or deed or by any of the innumerable wiles of women she engages the interest of the old lady so that the old lady will want to see her again. Following this up she plans her campaign to get more and more acknowledgments of acquaintance until, in time, authority creeps in. Then the dowager had better look out or the climber may climb above her and proceed to rule in her stead.

Far be it from us to suggest that chemists should lure bankers by tea parties and dances and auction or try to do so by spring hats or Chemists' Club coats, or even jewels galore. The instruments must be different, but there is a cousinship in method if they are to succeed. Bankers are on the lookout for investments just as the social dowager is looking for a larger kingdom. The dowager knows there are pitfalls, and that she must beware lest she give credence to persons who will not keep within the social traces. In like manner the banker is frequently lured by promoters anxious to get money into their enterprises, and the bankers' reputations depend upon their ability to steer clear of pitfalls. Now we venture the suggestion that chemists have not trained themselves to display their wares to the critical eye of the banker with the same care and wit that the social climber has availed herself of in breaking into society.

We know something of the wiles of the promoter, but the banker knows them a great deal better. He has juggled with figures and "conservative estimates" of profits anticipated, and prospective balance sheets until the banker has had his fill of that sort of business. He can cast up an imaginary balance sheet himself if he wants to. The attitude of mind that frightens him away most quickly is certainty of success by steps that he cannot understand. What he would like to know is the trade situation, manufacturing costs, the processes that have been already tried out and standardized, and those that are available but which have not been tried out and standardized. Give him this information so that he feels that he knows it and that he can clear up any doubts he may have in his mind to his own satisfaction by further investigation, and he will be as ready to go into chemical ventures as he is to underwrite a street railway enterprise or a mechanical industry. So far he has not been able to satisfy himself. This he must do for conscience' sake, and there are a thousand things that stand in the way of his innocent gaze. There is the tradition that chemical factories explode. Chemicals are poisonous. There is the danger of patent lawsuits. There is the problem of getting the best "formula"—one of the earliest questions that the banker is likely to ask. The formula or prescription theory is

locked very tight in his mind. The problem of opening the banker's mind is often baffling to the wits. So far the American banker has not been able to satisfy himself. The German banker has, and that is the difference—the difference that we have to meet. It is not a question of ability, American bankers are as able as any; it is a question of habit. Bankers all over the world are like the social dowagers (who are often their wives), in that while they may be led, they will not be driven. They are greatly influenced by fashions and styles in investments. It is useless to warn them that they are losing great opportunities. The promoters have worked that plan of persuasion so often that it does not impress them any more.

So, there are the bankers, ready and willing to go into chemical enterprises if only somebody they know and trust can show them the real situation. They do not speak or understand the chemists' language, and they have no chemical affiliations because nobody has set the fashion for it yet. As soon as it becomes known that one or two leading banking houses have as good and competent connections in chemistry as they have in law or in civil engineering, others will be as ambitious to follow the lead as are the women to have their skirts cut short, now that the style calls for it.

The problem, then, is to get this fashion into vogue, and since the bankers must start it, and chemists are not bankers, the method of induction would seem available. For this purpose we suggest that the meetings of banks' and bankers' associations offer the opportunity. Like all of us, bankers are anxious to learn, but they have an idea that information must be imparted to them in a language that they can understand. This idea or prejudice must be respected, otherwise they will close their ears. The committees on arrangements of the meetings of the local, State and national banking associations are eager to secure addresses that will be of interest to those present, and there are hundreds of opportunities every year for men who are enlightened in chemistry to tell them of the possibilities of chemical development within their territory. A few scatter-brained enthusiasts who say more than they know could kill these opportunities for years to come, but a number of the right men, talking to bankers on the occasions when we know that they would be glad to hear them, would do a world of good. The work should be looked upon as pure missionary effort, with no thought of reward for the speaker. In this attitude of mind he has but two rules to heed: That he draw no pictures that cannot be realized unto success under good management, and that he go through his address with a fine tooth comb and clean out every technical expression that he can. The man of books and ledgers and bills of exchange and warehouse receipts must be made as familiar with every term used as he probably is with kilowatt-hours and surely is with bales of cotton or tons of hay. He will not object if the speaker explains something that he already knows; he will like it; it will prove that the speaker is sound in knowledge and understanding. It is no insult to any audience to speak in words of one syllable.

Reader's Views and Comments

Hydrometallurgy of Zinc and Lead

Electrolytic Zinc

To the Editor of Metallurgical & Chemical Engineering:

Sir: Replying to the discussion by Mr. C. A. Hansen of our article on the hydrometallurgy of zinc and lead in 1915, we are gratified that our contribution was the means of bringing out definite data on such an important subject.

As to Mr. Hansen's statement that we were slightly inaccurate in attributing to him the use of only the "hydrate" process, at the time of writing our paper we were in possession of data on his more recent work, but as it had been given to us confidentially, we did not feel at liberty to mention it.

As regards the hydrate process in general, the idea of neutralizing the acid generated during electrolysis by some device or other was probably introduced into the United States some years ago by Carl Hering. Hering's patents were taken up by a California concern and the production of electrolytic zinc has been experimented on for many years in California. Most of the work done in that State was based upon the belief that the acid generated during the electrolysis must be neutralized, and consequently the ideas developed in connection with that work have shown great ingenuity in the different methods by which this object could be accomplished. For this reason we stated that we regarded the electrolytic work which has been done in Ontario as being very similar to that which has been done in California, and especially at Bully Hill. However, this is no reflection on the work which has been done there, as we believe that the work of Mr. Hansen and his associates has been a most important contribution to the commercial production of electrolytic zinc.

We note Mr. Hansen objects to our statement that an electrolytic zinc plant is not a poor man's proposition, and offers as evidence that we are in error regarding his estimated cost of a plant for reducing 200 tons of spelter per day from the Butte and Superior concentrates as being \$2,400,000. His estimate is doubtless very close to what the actual cost would be, and it was just this fact upon which we based our own conclusions. Perhaps it would have been better had we stated that the cost of an electrolytic plant is about the same as that of a retort plant for the same capacity. However, there are few companies in this country which can afford the outlay for an electrolytic plant. Hence our statement that such a plant is not a poor man's proposition, and our belief that at the present time the electrolytic zinc process is not well adapted to the production of zinc by small companies who wish to work the ores from small low-grade deposits, or even small high-grade deposits. An electrolytic plant calls for large deposits of favorable ore, and a steady production.

We believe that Mr. Hansen's communication constitutes a very important contribution to the literature of the subject of electrolytic zinc.

DORSEY A. LYON.

Salt Lake City, Utah.

Electrolytic Lead

To the Editor of Metallurgical & Chemical Engineering:

SIR:—Replying to the communication from Mr. Henry R. Ellis regarding what we had to say as to the hydrometallurgy of lead, we note Mr. Ellis claims to having had a prior knowledge of the facts underlying the brine process. We had not intended to give the

impression in our paper that we were presenting new facts unknown to previous writers, but rather that we had worked out a new process, based on facts worked out in three semi-commercial plants and in our own laboratories.

As a matter of fact, Mr. Ellis in his turn was not the original discoverer of the fact that lead can be extracted from its ores by the use of a strong brine. Several months ago in looking up the literature on this subject we found that in 1854 M. M. Bequerel of Paris had carried on experiments based upon the above facts. His work was reported in *Comptes rendus* (1854), 38:1095, and also in *Dingler's Polyt. Jour.* (1854), 133:213. Bequerel treated over 20,000 lb. of ore from Mexican and South American mines, as well as small lots of ore from the Erzgebirge, the Altai Mountains, and from different localities in France. He gave these ores a sulphatizing roast in the presence of salt, then leached out lead sulphate and silver chloride with a saturated brine. The brine was electrolyzed to recover the metals. This proposal of Bequerel's is almost identical with our present proposal, with the exception that modern commercial conditions are different from those existing at the time of Bequerel. As a source of electric current Bequerel only had primary cells, and it was doubtless the high cost of this item which caused his work to be dropped.

The process described by Mr. Ellis is different from the process mentioned by us in that he does not use a saturated solution of salt. We have found that the solubility of lead compounds falls off very materially as the solution is diluted, so that a half saturated solution has only 1/7 of the dissolving power of the saturated solution. Mr. Ellis, however, used hot solutions, which are capable of dissolving more lead than cold solutions, but we prefer the use of a cold saturated brine, which we feel is much closer to being commercially practicable.

DORSEY A. LYON.

Salt Lake City, Utah.

Hydrometallurgy of Lead

To the Editor of Metallurgical & Chemical Engineering:

SIR: Your correspondent Henry R. Ellis is the author of a statement in your issue for Feb. 1 that lead sulphate was extracted with brine in 1892. It is known that the process was employed earlier than that, as an English patent (No. 2316) was granted to a Mr. Wright in 1869 for identically the same operation, and it is not a long guess that a thorough search would reveal references to it in Pliny and Agricola.

There were two features in the work referred to by Lyon, Ralston & Cullen in your issue for Jan. 1, which apparently have escaped the observation of experimenters during the last fifty years. A diligent search has so far failed to discover any reference to them and there is accordingly still room for hope that they may have the element of novelty—but that is another story.

S. A. IONIDES.

Denver, Colo.

More Newspaper Science

To the Editor of Metallurgical & Chemical Engineering:

SIR:—The accompanying literary and scientific gem, clipped from a Western newspaper, sheds new light on copper hydrometallurgy as practiced by the energetic

and enterprising reporter. Speaking in detail of a certain process, he says:

"The insoluble compounds in the solution, such as oxides, come over in the stream of electrolysis and are deposited on the cathode plate in the form of pure copper and traces of other metals that may be present."

Thus another triumph is scored for electrometallurgy, and the gaiety of metallurgists proportionately increased. We are left in the dark, however, as to just how this "stream of electrolysis" is measured or controlled. How unfortunate that "pure copper" thus produced should be contaminated with "traces of other metals that may be present!" Something should be done to overcome this slight defect, and the point is brought to the attention of your readers in the hope that so valuable a process may shortly be perfected.

Denver, Col.

H. C. P.

Western Metallurgical and Chemical Field Pacific Coast Enters Electrochemical Field

The State of California is shortly to have a new industry.

The Great Western Electrochemical Company has recently been organized and incorporated in the State of California, for the purpose of manufacturing electrochemical products.

The first operation will be an electrolytic caustic soda plant in which caustic soda and chlorine products will be manufactured. The Moore Allan cell will be used, and bleach chambers such as used at the Dow Chemical Co. will be installed.

The future plans for this company are still somewhat indefinite, but it can be stated with certainty that other electrolytic products as well as electric-furnace products will be manufactured.

Ground is already broken for the new factory and the buildings and equipping of same is in charge of the Foundation Company of New York.

The location of the factory in Pittsburgh, Cal., 50 miles from San Francisco, is a very favorable one. The site, comprising some 40 acres, faces on the San Joaquin river which is navigable at this point by sea going vessels. In addition, service by the Southern Pacific and Santa Fe railroads is obtained.

The power supply is furnished by the Great Western Power Company, whose main transmission line passes in the close vicinity of the factory site.

The necessary salt and lime will be obtained from local supplies, and the needed fresh water is obtained in abundance in the San Joaquin river.

The plant will be in operation by July, 1916.

Directors of the new company are:

Mr. John F. Bush, formerly General Manager and Vice-President of Hooker Electrochemical Company.

Mr. Franklin Remington, President of The Foundation Company, New York.

Mr. J. W. Beckman, formerly of Niagara Falls, N. Y.

Mr. L. Bowen of Detroit, Mich.

Mr. Mortimer Fleishhacker of San Francisco, President of the new Electrochemical Company.

Mr. Louis Bloch, San Francisco, General Manager and Vice-President of Crown Willamette Paper Company.

Mr. Herbert Fleishhacker, President of Anglo-London Paris National Bank, of San Francisco.

Mr. A. Lilienthal, Secretary of the new corporation.

Mr. C. Hall.

The firm of Bush, Beach & Gent, 80 Maiden Lane, New York, will be the selling agents and will also maintain an office in San Francisco.

Annual Meeting Canadian Mining Institute

The eighteenth annual meeting of the Canadian Mining Institute will be at Ottawa, March 1, 2 and 3, 1916. The headquarters will be at Chateau Laurier Hotel. A symposium of flotation will be given by T. A. Rickard, E. P. Mathewson, Henry E. Wood and H. W. DuBois. Another feature of interest will be a paper on rock-crushing tests at McGill University, by J. W. Bell. The subject of education in mining and metallurgy will also receive attention from several contributors. The annual dinner will held on the evening of March 2, and on other days of the meeting visits will be made to places of technical interest in Ottawa.

Great Falls Electrolytic Zinc Plant

Work on the construction of the electrolytic zinc plant of the Anaconda Copper Mining Co., at Great Falls, Mont., is now in progress and will be completed as rapidly as possible, according to *The Anode*.

This plant will take the concentrates from the concentrator at Anaconda and will produce 100 tons of electrolytic zinc per day. The operations to be performed may be said, briefly, to be as follows: The concentrates are given an oxidizing roast, which renders the zinc and a small amount of other minerals soluble in a sulphuric acid solution. The roasted concentrates are, therefore, leached by such a solution and the impurities are precipitated by adding limestone and zinc dust as necessary. The purified solution is then sent to the electrolytic cells and the zinc is deposited as a sheet on the cathode.

The electrolytic zinc made by this process is much purer than spelter and has certain physical properties which spelter does not possess. Among other things, it is much more ductile and is particularly suited for use in the manufacture of high-grade brass.

Part of the slimes flotation plant building is being equipped with apparatus to treat 200 tons of zinc ore per day by the oil flotation process. The concentrates made in this plant will be treated at the Anaconda experimental zinc plant, which is to be enlarged, and will produce 25 tons of zinc per day.

Plans are now being drawn for a concentrator to treat 2000 tons of zinc ore by the oil flotation process, and it is expected that the plant will be completed by July.

The concentrates from this plant will be sent to Great Falls for treatment at the electrolytic zinc plant at the B. & M. Reduction Works.

Terms of Settlement of Arizona Labor Strike

After four months of idleness, during which time the employees of the Arizona, Detroit and Shannon copper companies lost their wages, and the companies lost the profit from about 6,000,000 lb. of copper per month, the labor strike in the Clifton-Morenci district of Arizona has been settled. The net result is a loss for all concerned, and the terms of settlement finally accepted are such as could have been obtained in the beginning.

The conditions under which work has been resumed are those offered by the managers of the several companies on Jan. 8, and are substantially as follows: The charters of Western Federation of Miners locals in Clifton, Morenci and Metcalf are surrendered in good faith, and the influence of outside agitators is eliminated. The men return to work under the former wage scale, which the managers offer to extend to meet the increased price of copper. It is understood that all workmen employed by the companies will receive full and adequate protection. The managers agree that no individuals of any nationality will be barred from re-employment because of their connection with the strike movement, except those who have been guilty of acts

of violence; and for this latter reason no more than ten will be discriminated against by the three companies.

The managers agree that upon resumption of operations and conditions becoming normal, they will meet committees of their employees with a view to adjusting any grievances or considering any questions which the employees may wish to bring up, the intention of the managers being to make conditions as satisfactory as possible for the employees.

The table below shows the rates of wages received by the principal classes of employees for the period Aug. 15 to Sept. 15, 1915, together with the rates which will be paid to the same classes of labor when the indicated prices for copper prevail.

Occupation	Hours	Wages, with Copper Selling At					
		Per Hour	Per Shift	Per Hour	Per Shift	Per Hour	Per Shift
Miners	7½	\$0.36½	\$2.74	\$0.39½	\$2.96	\$0.45½	\$3.41
Muckers and trimmers	7½	.28½	2.14	.31	2.33	.36	2.70
Timbermen	7½	.38½	2.83	.41	3.08	.47	3.52
Laborers (surface)	8	.24	1.92	.26½	2.12	.31½	2.52
Charge-wheelers	8	.26½	2.12	.28½	2.28	.33½	2.68
Skimmers	8	.44	3.52	.46½	3.72	.51½	4.12
Funchers	8	.33	2.64	.35	2.80	.40	3.20
Laborers	8	.24	1.92	.26½	2.12	.31½	2.52
Carpenters and electricians	8	.54	4.32	.57½	4.60	.62½	5.00
Machinists and boilermakers	8	.57	4.56	.60½	4.84	.66½	5.32

Non-Ferrous Metal Market

Feb. 10.—The metals continue in their strong position. The only decline recorded during the last two weeks was one of about ½c. in tin. The other metals either remained unchanged or registered advances. The extraordinary situation in copper has forced that metal still higher, while most of the other metals are scarce to a greater or less degree for early deliveries.

Copper.—Producers are sold up for several months ahead, in some cases up to July and August and deliveries this side of May or June are hard to obtain. The market has risen steadily since our last report and quotations are now 27 to 28c. for nearby deliveries and 26 to 27c. for June and later deliveries. Conditions abroad are reported to be about the same as ours and a scarcity has forced prices up. Electrolytic is quoted in London at £131 spot. Rumors are afloat of heavy foreign buying for shipment now and after the war. England is said to have bought 100,000 tons and Germany a large amount for later shipment. Whether the present market is due to these purchases is a matter of conjecture, but it is thought by a number of authorities that this is the case. At any rate the domestic consumption is very heavy and articles in which copper is used will naturally be higher priced.

Tin.—Good sales of tin were reported the last few days in January. Early deliveries and futures have not been hard to buy. Stocks on Jan. 31, figured from the deliveries, were 2401 tons. Arrivals in January were 4430 tons. There is no scarcity of tin, either spot or en route. The market during the first ten days in February has been dull. Straits is quoted at 41.25 f.o.b.

Lead.—Up until Feb. 8 lead remained dull. On that day a good demand appeared for both prompt and future deliveries, and lots for sale by outside parties not connected with the Trust are commanding a premium. The Trust price is still 6.10 New York.

Spelter.—Buying of spelter was scarce up to Feb. 8, when large purchases were made. Deliveries up to May are being sold. Second quarter deliveries are quoted at 16.50c. St. Louis, March at 18.50, February at 18.75. Spot spelter is 19c. at St. Louis and 19.17½ to 19.42½ at New York.

Other Metals.—Aluminium advanced 1c. on good in-

quiry and is now quoted 54.00 to 56.00. Antimony was in good demand on Jan. 31, after two weeks' dullness. Supplies are scarce and the quotation is now 43.50 to 44.00, with the market firm. Silver moved up and down within a narrow range and is now quoted at 56½. Platinum is still hard to quote, owing to the scarcity, and \$88 to \$100 per oz. remains the nominal price. Quicksilver is quoted at \$275 to \$300 per flask.

The Iron and Steel Market

The steel market has become distinctly quiet as to strictly new buying, but on the whole there is as heavy specifying as ever on open contracts. In some quarters the slowing down in the rate of new buying is interpreted as suggesting that a change has occurred in the general situation, but the majority view is that the slowing down is due to the physical condition that the market is already sold out.

The future of the mills for the purpose of forecast may be divided into two periods, that for which they have specific orders on books, or orders practically assured, and the later period for which consumptive demand must develop, on the basis of higher prices than have hitherto obtained. With the average mill the first period comprises about six months. Some mills have definite orders and specifications on books for fully six months, while others have such business for a shorter period, with every indication that orders will continue heavy for a time. The great bulk of this specific business is at prices much below those now ruling. There are some specifications yet to be filled that were filed against fourth-quarter contracts, and the contracts now being specified against are as a rule at much lower than current prices, averaging in the case of bars, plates and shapes about 1.45c., while the present market is 2.00c. on bars and shapes and 2.10c. on plates.

It is natural that doubt should be entertained whether consumption will be seriously curtailed in future when buyers must pay the present high prices. It is a question not for nearby months but for the second half of the year, perhaps only for the fourth quarter. The prospect for heavy consumption is made favorable by the fact that the present demand is very well distributed, and appears to be chiefly for the filling of everyday requirements rather than for large construction projects in which costs are carefully considered. It is much more difficult than usual to trace to its ultimate use the steel being shipped. The consumption of standard rails is extremely light and structural tonnage is far from heavy. There is feverish activity among builders of machinery and automobiles, lines of consumption in which price cuts almost no figure. It is interesting to observe that there is but one steel commodity that has not advanced in price, standard steel rails for domestic roads, and it is that commodity which is being produced at the lowest rate. Rails for export have been selling at relatively high prices, and rail exports are at a record rate. In this one instance at least the price has no influence upon the demand.

Exports of iron and steel returned by weight were 363,000 gross tons in November, slightly more than in October, but less than in any of the three months preceding. There is no reason to suppose that the consumption of steel in the manufacture of export products that are not returned by weight has increased from the average of the months of July to November inclusive. In that period the exports that are returned by weight represented a rate of about 4,000,000 tons of finished rolled steel per annum. An estimate

of 3,000,000 tons of finished steel a year would probably be high for that consumed in the manufacture of the indirect exports, including loaded and unloaded shells, machinery, automobiles, railroad rolling stock, etc., so that it does not appear that finished steel made for all export purposes is at a rate higher than about 7,000,000 tons at the outside. The current production is at approximately 29,000,000 tons.

The steel trade is so extremely prosperous at present that interest centers not so much upon the bearing that current events may have on the present or the nearby future as upon the bearing they have upon the course of trade in the more distant future. Obviously the steel mills will be under pressure for more than six months, but whether they will be under pressure for nine months, a year or three years is another matter. Many of the mills are uncomfortably over-sold at present and would require months even of a quiet market to recover. What is probably an important indication for the future is that at the present moment the demand for prompt material, which commands premiums over forward deliveries, is as great as it was 30 days ago and greater than it was 60 days ago. While the large mills do not accept premiums for prompt shipment, the smaller mills make this their rule. In plates, for example, carloads for shipment within a week or two are bought freely at 3.00c., while orders for 100 to 500 tons are common for delivery over 90 days, at about 2.50c., these prices comparing with the regular price of 2.10c. made by large mills for delivery at their convenience.

Pig Iron

The dullness that characterized the pig-iron market in January has since developed into absolute stagnation, with signs in some quarters that prices are perhaps a shade easier, though they are not quotably lower. Pig-iron production by both steel interests and merchant furnaces has increased further, and is now at the rate of about 39,000,000 tons per annum, a rate which a year ago no one thought the furnaces could possibly compass. The question is the one which so often develops in the pig-iron market, which party, the buyers or the sellers, can hold out the longest. We repeat former quotations: No. 2 foundry iron, delivered Philadelphia, \$19.75 to \$20.25; f.o.b. furnaces, Buffalo, \$18 to \$18.50; delivered Cleveland, \$18.80; f.o.b. furnaces, Chicago, \$18.50; f.o.b. Birmingham, \$15; at valley furnaces, 95 cents higher delivered Pittsburgh; Bessemer, \$21; basic, \$18 to \$18.50; No. 2 foundry, \$18.50 to \$19; forge and malleable, \$18 to \$18.50.

Steel

There has been a slight softening in the unfinished steel market, to the extent that odd lots of billets and sheet bars can now occasionally be picked up for fairly prompt shipment, whereas until very recently there was practically no steel to be had except at prohibitive prices. While the market is still not clearly defined, it is probably represented better by \$33 for Bessemer and \$35 for open-hearth billets and sheet bars, f.o.b. maker's mill, Pittsburgh, or Youngstown, than by any other figures. We note sales of three lots of sheet bars aggregating about 1500 tons for prompt shipment on a basis of a trifle under \$35, f.o.b. maker's mill, Pittsburgh, but it is only occasionally that such lots can be picked up. Rods are quotable roundly at \$45, Pittsburgh, but are largely nominal at that figure.

Finished Steel

On Feb. 4 the Carnegie Steel Company advanced its prices on bars, plates, shapes and hoops by \$2 a

ton, the advanced prices readily becoming the general market. For early shipment plates are bringing 2.50c. to 3.00c., bars commanding 2.25c. to 2.50c. Regular mill prices are given below, f.o.b. Pittsburgh, unless otherwise noted, and are for delivery at mill convenience.

Rails, standard sections, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 2.10c.

Shapes, 2.00c.

Steel bars and bands, 2.00c., base; steel hoops, 2.20c., base.

Iron bars, Philadelphia, 2.409c.; Chicago, 1.90c.; Pittsburgh, 2.20c. to 2.25c.

Plain wire, 2.05c., base; galvanized wire, \$2.75c.; wire nails, 2.20c. per keg, base; painted barb wire, 2.35c.; galvanized barb wire, 3.05c.

Sheets, blue annealed, 10-gage, 2.65c. for Bessemer, 2.75c. for open-hearth; black, 28 gage, 2.60c. for Bessemer, 2.75c. for open-hearth; galvanized, 28-gage, 4.75c.; painted corrugated, 28-gage, 2.80c.; galvanized corrugated, 28-gage, 4.80c.

Tin plate, \$3.75 to \$4 for 100-lb. cokes.

Steel pipe, $\frac{3}{4}$ to 3-in., black, 76 per cent off list; galvanized, 60½ per cent off list.

Boiler tubes (less than carloads), 3½ to 4½-in. 64 per cent off list; iron, 60 per cent off list.

Structural rivets, 2.70c.; boiler rivets, 2.80c.; cold-rolled shafting, 45 per cent off list; cold-rolled strip steel, 4.00c., base.

The Flotation Conference at the University of Kansas

At the suggestion of Mr. Dorsey A. Lyon, metallurgist for the United States Bureau of Mines, the first gathering of metallurgists and mining men to consider exclusively the rapidly growing subject of flotation came together on Jan. 28 and 29 in the University of Kansas at Lawrence. The Kansas institution was agreed upon as the first meeting place of the conference because of its central location and because of the pioneer work of its Division of State Chemical Research in investigating the application of flotation to zinc recovery within the State.

The underlying object of the conference was to discuss the problems which are yet to be solved in the process of flotation and more particularly to consider the research work now being conducted in various universities and mining schools with the object of encouraging further research and preventing useless duplication among the various investigators concerned.

Among the visitors in attendance at the conference were Messrs. D. A. Lyon and O. C. Ralston of Salt Lake City, representing the United States Bureau of Mines and the University of Utah; Dr. A. L. McKee, director, and Mr. Charles Clayton of Rolla, Mo., representing the Missouri School of Mines; Mr. R. C. Palmer of Madison, Wis., representing the United States Forest Products Laboratory, and Mr. C. A. Wright of the Bureau of Mines, stationed at Joplin, Mo., representing the Joplin Zinc District.

The University of Kansas was represented by Prof. W. A. Whitaker, director of the Division of State Chemical Research, which is prosecuting several flotation investigations; Mr. George Belchic, flotation investigator, and by Messrs. Roy Neal, S. F. Farley and L. E. Van Velzer, assistants in flotation work. Others present from the University of Kansas were Profs. E. H. S. Bailey, C. F. Nelson, A. C. Terrill, H. C. Allen, G. W. Stratton, W. H. Twenhofel, A. H. Sluss and R. L. Crider. Letters were read from more than thirty pro-

fessors of mining and metallurgy throughout the country expressing their approval of such a conference and regretting their inability to attend.

In addition to several informal conferences which were held on the 28th, two regular meetings were held on Saturday, Jan. 29, with Professor Whitaker acting as chairman. The morning session continued from 9.30 a. m. to 12.30 p. m. and the afternoon session from 2 p. m. to 5 p. m. The morning session was consumed by the three following papers and the resulting discussion:

1. "Some Things that May Be Accomplished by a Conference on Flotation," Mr. D. A. Lyon, United States Bureau of Mines.

2. "Proposed Research on Flotation," Dean Milnor Roberts, University of Washington (read by Dr. A. L. McRae). Discussion led by Messrs. Lyon and McRae. In the course of his remarks, Dr. McRae stated that the Missouri School of Mines was engaged in making a complete bibliography on flotation and that this would be completed soon. Mr. Lyon urged the publication of such a bibliography.

3. "The Theories of Flotation," Mr. George Belchic, University of Kansas. Discussion led by Messrs. Ralston and Whitaker.

The discussion on this paper was very full and brought out several new points on theory, especially as regards the relation to flotation of colloid knowledge and surface tension phenomena. The theoretical and practical flotation questions now being investigated at the University of Kansas were reviewed. The discussion was succeeded by three informal talks: Dr. C. F. Nelson of the University of Kansas spoke on colloids; Mr. R. C. Palmer of the United States Forest Products Laboratory spoke of the desire of his laboratory to help in evolving the proper flotation oils as products of wood distillation; Mr. Charles Clayton of the Missouri School of Mines reviewed briefly some of the work which has been done in that institution.

The afternoon session was devoted almost entirely to the formulation of a questionnaire on theory, which, it is intended, shall be sent to all institutions that are engaged in investigating flotation problems. A set of questions was proposed by Mr. O. C. Ralston, and in the general discussion which followed the list was increased by the addition of other questions. At this time, Mr. Roy Neal of the University of Kansas gave some of the data which he had obtained in his experiments on surface tension and interfacial tension. The closing feature of the conference was a talk by Prof. A. C. Terrill of the University of Kansas on "Some Observations on Flotation Practice." Following this talk the conference went into executive session for a few minutes and then adjourned.

On Friday evening, Jan. 28, a "smoker" was given in honor of the visitors at the University Club, at which talks were made by Messrs. Lyon, Palmer, McRae and Whitaker.

American Electrochemical Society New York Section

Electrochemical War Materials — Electrolysis of Underground Structures.

For the meeting of Feb. 11, Dr. C. G. Fink, chairman of the New York Section of the American Electrochemical Society, had arranged an unusually interesting, instructive and timely program, in the form of a symposium of papers on electrochemical war supplies. The attendance at the meeting was very good. Limitations of time and space force us to reserve the full report of this meeting for our next issue. The paper by Dr. G.

Ornstein on electrolytic chlorine presented in this symposium is published in full on page 215 of this issue.

For the evening of March 10, 1916, the American Institute of Electrical Engineers has extended a courteous invitation to the New York Section of the American Electrochemical Society for a joint meeting in the United Engineering Societies Building. The subject of discussion will be electrolytic corrosion of underground structures.

Necessity for an American Dye-Stuff Industry

At the third National Foreign Trade Convention held at New Orleans, La., from Jan. 27 to 29, Mr. HENRY HOWARD, vice-president of the Merrimac Chemical Company, and chairman of the executive committee of the Manufacturing Chemists' Association of the United States presented an interesting paper on "The Necessity of an American Dyestuff Industry to Aid Export Trade in Textiles."

The speaker pointed out that the stoppage of importation of dyes from Germany "has been disastrous to what we all desire—namely: an increase in our foreign trade in textiles. Many textile mills have been obliged to curtail their output at a time when, if we had been independent of other countries, with a dye industry well established, these same mills could have been running night and day manufacturing goods for export and establishing foreign connections by aid of which a considerable percentage of this business might have been retained after the close of the war."

The speaker stated that the fact that there is no adequate coal tar industry in this country can not be charged against the Democratic party but is due "to the strenuous effort of the foreign manufacturers and American importers, ably assisted by the short-sighted selfishness of these same textile manufacturers who are now the principal sufferers."

The speaker pointed out that the American dyestuff industry gave promise in 1882, but then came the fatal tariff reduction in 1883. Now the American textile manufacturers stand ready to co-operate in any way possible in order to establish a permanent coal-tar industry within the United States.

Mr. Howard compared the present condition of textiles in this country with that of iron and steel. "The latter industry, thanks to the consistent protection which for years was extended to every branch of the business, is now absolutely independent of the rest of the world in its ability to manufacture all standard grades of iron and steel products in this country, with the result that not only are all American users of iron and steel products getting their supplies as regularly as before the war began, but a large export business is being developed as the result of the paralysis of this industry abroad. In textiles the saving of a possible 4½ cents on a hundred dollars' worth of product has resulted in so throttling the textile industry that it is having hard work to supply our local markets, much less to gain a strong foothold in the foreign markets formerly supplied by the belligerent countries."

Mr. Howard considers that a permanent non-partisan tariff commission is necessary. Further, unfair competition of foreign dye manufacturers must not be permitted. Finally Mr. Howard pointed out the intimate connection between the manufacture of dyes and explosives. A complete coal-tar dye industry in this country is necessary for the sake of preparedness.

Mr. Howard was not alone in referring to the desirability of an increased export trade. Other speakers emphasized the stabilizing influence which export trade has in any industry.

The Calcination of Zinc Carbonate

BY WILLIAM P. SIMPSON

Calcination in general has been practiced as long as quicklime has been known; it consists simply in the conversion of carbonates into oxides by the application of heat.

In the particular adaptation to zinc carbonate the process involves heating the ore to such a temperature as will drive off carbonic acid without volatilizing zinc, leaving zinc oxide, with its decreased weight per unit of zinc, in place of the original carbonate.

Aside from better market value for ores of higher zinc content, the object of calcination may be one of several, depending upon the locality in which the operations are carried on or upon the subsequent treatment of the ore. In the former case the reduction of transportation cost effected by this form of concentration is the desired end. In the latter it is the lowering of fuel expense, decrease in bulk of material handled or the time element involved in the further working of the ore.

For instance, the first mentioned incentive may be illustrated by the case of calcination in Mexico, to accomplish a saving in freight charge on the long haul to the Oklahoma smelters. Illustration of the latter object may be had in Belgium and Germany, where calcination is employed before retort smelting, thus saving time in distillation, as otherwise a large part of the smelting period would be consumed in driving off CO_2 before distillation of zinc could begin. Further, the smelting of calcined ore would increase the capacity per retort due to the previous concentration of the ore by calcination. Formerly it was considered essential to get rid of CO_2 before retorting carbonate ores. Of late years, however, American smelters have charged crude carbonates into their retorts, proceeding with distillation as when roasted blende is used.

Labor Cost Limits Use of Process.

Factors in the practicability of employing calcination in any given case are the relative cost of labor and fuel. As in the early history of sulphide roasting, so in the calcination of zinc carbonate, hand work has thus far given better results than mechanical treatment. This fact has retarded the use of calcination in this country, where labor is the big item in operating cost, fuel being comparatively cheap. In Europe labor is cheap and fuel expensive; hence at the expense of labor and the saving of fuel, calcination precedes retorting as previously explained, a cheaper grade of coal being used in calcination than for smelting.

The history of calcining zinc carbonate begins with the exploitation of such ore in Algeria, Greece, Italy, Spain and the island of Sardinia. In these countries calcination is practised at the mines. For many years the smelters of Belgium and Germany have employed calcination before retorting. In the United States the only locality where the process is being conducted, as far as I am aware, is at Arden, Nevada, where purely mechanical handling has thus far resulted in very incomplete, but profitable, calcination. For several years Oklahoma smelters have been receiving increasingly large shipments of calcined zinc ore from Mexico, and until the European war broke out Mexico had for ten years shipped calcined ore as ballast to Europe.

Beginning with the chemical or laboratory side of the subject, there is one ore which is of chief importance, viz., smithsonite, ZnCO_3 . The molecular weight of this carbonate is 125.4; that of zinc oxide is 81.4. This gives a ratio of carbonate to oxide of 1:0.649, or roughly 1:0.65. Assuming the zinc in an ore assaying 32.5 per cent to be pure smithsonite, the zinc percentage after calcination will be $32.5 \div 0.65$, or 50 per cent.

Experience, however, shows that this method of determining the zinc content which may be expected from calcining any particular ore is not satisfactory. Several conditions explain why this procedure may not be confirmed in actual practice. First, the ore may not contain its zinc as pure carbonate; second, calcination is rarely complete, and a product is seldom obtained which would be comparable to what is known as a sweet roast in desulphurization, from 0.4 per cent to 1.5 per cent of carbonate often remaining in the best calcine. On the other hand, there are often carbonates other than zinc in the ore, such as calcium carbonate. The decomposition of these may cause a decrease in weight and consequent increase in zinc in the calcine beyond the percentage that would be indicated by this method of calculation.

Laboratory Calcination Assay

The relation of the calculated result to that obtained in actual practice may be determined by a laboratory calcination assay, as follows: Ten grams of the powdered crude ore is weighed into a 3-in. scorifier or saucer-like porcelain dish and spread in as thin a layer as possible. The dish is then placed in the muffle of an assay furnace at such temperature as will bring the ore to a dull red glow in ordinary daylight. The muffle door is left open and the furnace doors are so manipulated as to cause the greatest draft through the muffle and produce the best oxidizing conditions. A little practice and experience based upon comparative tests and assays will enable the assayer to gage the temperature by the eye. Too high a temperature, above 920 deg. C., results in loss of zinc; too low a temperature, below 300 deg. C., or too short a time, will result in incomplete calcination. Two hours in the furnace under proper conditions will give satisfactory results.

At the expiration of this time the assay is removed from the furnace, and when cool it is returned to the scale pan of the balance, with the same ten-gram weight on the opposite pan. Equilibrium is now established

TABLE I

Laboratory calcination assays, showing comparison of different methods of calculating percentage of zinc in the calcine.

No.	Crude Ore, Per Cent Zinc	Calcination Loss, Per Cent	Complement of Calcination Loss	Per Cent Zinc Calculated from Calcina- tion Loss	Per Cent Zinc Assayed by Assay	Per Cent Zinc Ore Was Pure Carbonate (% Zn $\div$ 0.65)
1	16.7	13.7	86.3	19.4	19.1	25.8
2	19.7	14.3	85.7	23.0	22.7	30.2

Ideal Charge

Ore Class	Quantity	Class Factor	Resultant
1	20 barrows @	4	80
2	5 barrows @	3	15
3	2 barrows @	2	4
4	1 barrow @	1	1
	28		100

TABLE III

Showing variation limits in charges and their effect on capacity. One barrow-load weighing about 400 lb.

Resultant	Charges of 28 Barrows Each	Capacity Tons
95	3½	20
97	4	..
99	4½	..
101	5	..
103	5½	..
105	6	..
107	6½	36

by adding the necessary small weights to the pan containing the assay, and these weights indicate directly the percentage loss of weight by calcination. This is called the "calcination loss." Now the complement of this calcination loss (80 per cent in the case of 20 per cent loss) divided into the zinc percentage of the crude ore will give a very close approximation to the zinc percentage that may be expected from calcination on a commercial scale. The actual operation in kilns generally results in still greater calcination loss than the assay shows.

Table I contains the results of ten laboratory calcination assays, and shows comparatively the zinc content of the calcine as determined (a) by the method of calcination just given; (b) by actual assay of the calcine; and (c) by calculation on the assumption that the ore is pure carbonate. The first two sets of figures agree quite well and show the reliability of the calcination assay. The third set, on the other hand, show by contrast the misleading results obtained when assuming the zinc to exist as pure carbonate.

In practice, daily samples of crude ore and calcine are assayed for zinc and calcination loss, to control the operation of the furnace or kiln, just as in lead smelting assays of bed samples and slags inform the metallurgist of the operation of his blast furnace.

Three Essentials to Success

Turning now to the practical application of the process, the method and equipment are very simple; yet three points are of such vital importance that calcination has proved a failure in the hands of novices. These three points are: 1—sizing of the ore; 2—form of furnace or kiln; 3—manner of charging.

For calcining in kilns the ore is passed over grizzlies or screens to produce the following four grades:

Class 1: oversize of a 3-in. grizzly; from 3 to 5 in. in diameter, averaging 4 in.

Class 2: undersize of a 3-in. grizzly, remaining on a 1-in., averaging 2 in.

Class 3: undersize of a 1-in. grizzly, remaining on $\frac{1}{2}$ -in. screen, averaging close to 1 in.

Class 4: undersize of $\frac{1}{2}$ -in. screen, averaging about $\frac{1}{4}$ in.

For satisfactory calcination in kilns, experience has

shown the necessity of a certain interior shape or form to permit the charge to descend in uniform horizontal zones and to discharge promptly at the bottom. A vertical section, side view and ground plan of a kiln are shown in Figs. 1, 2 and 3. The exterior is hexagonal in form, about 16 ft. in diameter and 20 ft. high. The feed floor is level with the top. Looking down into the kiln, the interior resembles an ordinary round cistern, though less contracted at the top. The curve of the interior is determined by two radii. It allows for the expansion of the ore in calcining and produces a choking effect at the bottom above the four discharge doors. On the bottom or floor of the kiln is a central concrete cone covered with sheet iron, the apex being at a point above the arches of the four doors. This cone insures an even descent of the kiln contents and a complete removal of the finished product through the four doors.

Method of Charging a Kiln

The initial charging of a kiln consists in building up with wood from the kiln floor to a point above the arches of the doors. The first charge of ore is placed on the wood, consisting of successive layers of the different classes. Class 1 is spread evenly over the wood; then Class 2 is carefully fitted into the interstitial spaces on Class 1 and built up to a layer of desired thickness. Class 3 is superimposed on Class 2, and finally the fine ore, or Class 4, is added, making a level floor of gravel-like structure. Upon this foundation the regular charging begins; first broken charcoal or coal, about 4 per cent of the weight of the ore-charge, followed by layers of ore as above described, beginning with coarse and finishing with fine. In this way zone upon zone of fuel and ore is built up in the furnace, great care being taken in placing the successive layers by hand so as to form porous charges that will ignite readily after combustion is started in the wood at the bottom.

After calcination is started, the product is removed periodically at the bottom of the kiln through the four doors simultaneously, and immediately a new charge is placed in the furnace at the top. The quantity withdrawn at any one time is about equal to the quantity in a charge, and in this way the content of a kiln is kept constant and at a level about one foot below the feed floor. In a kiln 20 ft. high there will be from 8 to 10

FIGS. 1 AND 2—VERTICAL SECTION AND SIDE VIEW

FIG. 3—GROUND PLAN

zones of the type described, each becoming ignited from the one below. Thus, after once blowing in the furnace the process continues indefinitely, the addition of a new charge coinciding with the periodic removal.

Often a kiln will run thus for months much the same as an iron or lead blast-furnace. The heat, however, is not intense, and the men engaged in placing a new charge stand in the top of the kiln without discomfort. Each kiln of the type described has a capacity of from 20 to 36 tons of product per day, depending on the nature of the ore and the proportions of the several classes or grades comprising the charge. A kiln will hold 90 tons of crude and 70 tons of calcined ore. The charges are carefully weighed, and the operation is controlled by the proportion of each class of ore charged.

Empirical Calculation of Charges

The empirical nature of the calcination process as conducted in kilns is illustrated by the method of calculating charges. An ideal charge is given in Table II. This system was developed in the pioneer work with the particular type of kiln above described. Each of the four classes of ore is given a factor in reverse order to its class number. Thus Class 1 has a factor of 4; Class 2 a factor of 3; Class 3 a factor of 2; and Class 4 a factor of 1. The unit of quantity is the wheelbarrow load, about 400 lb. Experience developed the fact that the number of barrow loads of each class could be varied, provided the total number was maintained at 28. As shown in Table II, an ideal charge gives a sum of "results" equal to 100; but the satisfactory working of the kiln was found to admit of such changes as would give a variation in the sum of results between 97 and 107. Different types of charge naturally affect the total number of charges per 24 hours. As shown in Table III, the variation of resultant from 97 to 107 gives a variation in daily tonnage from 20 to 36 for the particular type of kiln under consideration.

Rotary Kilns for Fine Ore

In preparing ore for the kiln process of calcination there results a superabundance of fine material which cannot be used in the charge, for the whole content of the furnace must be porous enough to afford proper draft. This surplus of fine ore must be calcined in a rotary inclined kiln, the charge being fed at the upper or cool end and gradually working down toward the fire-box, in front of which the calcium product is discharged. Oil or coal is used as fuel for these rotary kilns. Calcination is less complete, however, than in the vertical type. The cost for labor is much less than in the method first described, and this suggests that some mechanical method of calcination must be devised if the process is to be utilized as a means of concentration in this country, where the labor cost is high.

The question of dust losses has been raised in connection with calcination as a possible objection to the process. There is, of course, some dust loss, and precautions must be taken to avoid loss of fine material in transportation. Nevertheless the process has been found highly profitable in certain places. Another objection is that the handling of the calcine is disagreeable to laborers, particularly when there is much lime in the ore. When lime forms a substantial constituent of the ore it is not advisable to expose the calcine to the weather for a long time, as that part of the limestone which has been altered in the kiln will slake and increase in weight and consequently reduce the percentage of zinc in the calcine. The zinc, however, suffers very little in this regard, and calcines transported by rail to the Atlantic seaboard and thence by boat to Europe, often several months en route, show little alteration.

Denver, Colo.

Photochemistry

A Lecture Delivered Before the Teknik Club in Denver

BY HARRY A. CURTIS, PH.D.

Everyone has observed that light may bring about, or at least hasten, certain chemical actions. That growing plants require sunlight, that wall-paper fades, that laundered linen is whiter when dried in direct sunlight, that our hands and faces tan in the summer, these are facts of photochemistry too evident to be overlooked. To a lesser degree the photochemical processes of photography are known to the layman, but the modern science of photochemistry is known only to a few investigators. It may, therefore, be of some interest to the readers of this journal to consider the broad outlines of a branch of chemistry which offers great promise of becoming vastly important to man.

It is not the purpose of the present paper to trace the development of the science of photochemistry, but rather to summarize the results which research in this field has yielded and to point out certain large problems which are now occupying most attention.

To discuss a highly specialized branch of any science in language which shall not be so technical as to bewilder the average reader of a scientific journal, and yet not lose that precision which a special nomenclature brings to any science, is no easy task. The attempt will be made in this article to steer a happy middle course between the inaccuracies which inhere in a popular discussion of a technical subject and the formidable language behind which every science finally takes refuge from popular attack.

The term photochemistry has unfortunately become associated with the better known word photography. It must therefore be pointed out here that photography is but one branch of a very much wider science, photochemistry. Photochemistry has been defined as the study of the effect of light on chemical reactions, the term light being used in its broader meaning to include the infra-red and ultraviolet regions of the spectrum.

Visible light includes waves of radiant energy whose lengths* lie roughly between 800 μ and 400 μ . This range is but a very short piece of the total spectrum of radiant energy, which is now known to extend from waves less than a millionth of a millimeter long up to those having a length of several hundred miles. It is instructive to give in Table I the various parts of this spectrum which have been investigated to date.

TABLE I—SPECTRUM OF RADIANT ENERGY

Wave-Length	Name of Wave	Investigator
0.01 μ to 1 μ	Röntgen or X-rays	Röntgen, 1895
1 μ to 100 μ	Uninvestigated	
100 μ	Shortest ultraviolet	Schumann, 1893
200 μ	Ultraviolet rays	Cornu, 1878
200 μ to 400 μ	Ultraviolet rays	Ritter, 1801
400 μ to 800 μ	Visible rays	Newton, 1666
800 μ to 1 μ	Ultrared rays	Herschel, 1800
1 μ to 10 μ	Heat rays	Lansley, 1886
10 μ to 61.4 μ	Heat rays	Rubens, 1896
100 μ	Heat rays	Rubens, 1910
218 μ and 343 μ	Heat rays	Rubens, 1911
343 μ to 1 mm	Uninvestigated	
4 mm	Shortest electrical waves	Lampa, 1895
6 mm	Electrical waves	Lebedew, 1895
		Hertz, 1889
1 cm. to 10 m.	Electrical waves	Lodge, 1890
		High, 1894
10 m. to 1 km	Electrical waves	Felderssen, 1892
1 km. to 100 km.	Electrical waves	Tesla
100 km. to 1000 km.	Electrical waves	Lodge, 1888

It will be seen in Table I that if the visible portion of the spectrum be called unity, then the total range represented in the table will be 2.5×10^4 . To get an idea of the magnitude of this ratio, suppose the length of

*1 μ = 0.001 millimeter;

1 $\mu\mu$ = 0.000001 millimeter.

the visible spectrum to be a meter. Then the total length represented would span the distance from earth to sun about 170 times. It is probable that radiant energy of every wave length will be found to have an effect on chemical reactions. As yet, however, research in this line has been almost completely limited to the visible and ultraviolet parts of the spectrum, to heat rays, and, in very recent years, to a few scattered investigations in the region of very short waves.

Available Sources of Light

Our greatest source of light is, of course, the sun. Professor Luther estimates that the sun delivers continuously to the earth about 200,000,000,000 hp., which is about 1,000,000 times more than is generated by all the engines on earth. Of this enormous quantity of energy, plants utilize a small portion, part is reflected away from the earth, and the balance is dissipated as heat. To store up and utilize a larger part of this energy with which the sun floods the earth is one of the dreams of photochemists.

While it is probable that any successful commercial process of photochemistry must utilize sunlight, it has been found that sunlight is a most unsatisfactory source of light for purposes of photochemical research. The difficulty is, of course, that the intensity of the sunlight is never constant for more than a few minutes at a time. Aside from this, the earth's atmosphere filters out the shorter waves of light, the very ones which are the most effective in most photochemical processes.

Of the various artificial sources of light, only a few are of sufficiently high intensity to be used in photochemical studies. The electric arc has sufficient intensity, but is difficult to keep burning steadily. The same difficulty is met with in the case of the electric spark, although several successful pieces of research have been accomplished using the spark as a light source. The Nernst glower burns steadily, and gives a continuous spectrum, but the light is not rich in the short waves. By far the most successful lamp for purposes of photochemical research are the mercury-vapor lamps. These are easy to operate, and give an intense light which is very rich in short waves. The spectrum of the light emitted is, of course, discontinuous. This is an advantage where it is desired to carry out research using monochromatic light, for if the light be spread out with a prism, any particular line may be used as a light source by simply screening off the rest of the spectrum. Where all the light is to be used, the spectrum may be enriched by replacing the mercury with an amalgam.

If the shorter waves of the mercury-vapor light are to be utilized, however, the lamp may not be constructed of ordinary glass, for this is not transparent to waves shorter than about 350 μ . Many attempts have been made to prepare glass which should be more transparent to the shorter waves. These attempts have been successful to the extent that glass has been produced at the Jena works having a transparency extending to nearly 250 μ . This, however, only partially solves the problem. There are indeed very few materials which do possess the desired properties. The lower limits of transparency of a number of common materials are given in Table II.

Of these materials, quartz is the one best adapted, and since the methods of working quartz have been developed, this material has found wide use in photochemical research, both in the manufacture of lamps and of all sorts of reaction vessels.

The Measuring of Light

The problem of measuring light in photochemical research is one which differs radically from the meas-

TABLE II—THE LOWER LIMITS OF TRANSPARENCY

FLINT GLASS.....	One centimeter thickness transmits from 50 to 80 per cent at 350 μ . Less than 1 per cent is transmitted at 305.
UVIOL GLASS.....	Lower limit at 253 μ .
FLINTOITE.....	One centimeter thickness transmits 83 per cent at 186 μ and the transparency is still high at 100 μ .
ROCK SALT.....	Transparency is high at 186 μ .
QUARTZ.....	Transmits 94.2 per cent at 222 μ and 67.2 per cent 186 μ ; at beyond 186 μ the transparency falls off rapidly.
CALCITE.....	Less transparent than quartz for short waves.
MICA.....	Strongly absorbs the short waves.
WATER.....	Transparency is high at 193 μ . At 186 μ it is less transparent than is quartz.
GLYCERINE.....	Transparency is high at 240 μ .
CANADA BALSAM.....	Transparency is high at 330 μ .
GELATINE.....	Transparent down to 253 μ .
AIR.....	Transparency is high at 194 μ ; at 186 μ the absorption is very high, and no waves shorter than 165 μ are transmitted.

uring of light for ordinary illuminating purposes. In the latter it is the visual result which is in question, and therefore any of the visual photometers may be applied. In photochemistry, however, the problem is usually to determine the rate at which radiant energy is being delivered to the reaction vessel. This at once eliminates all visual photometers, for the human eye is not equally sensitive to light waves of all lengths. It is most sensitive to yellow-green light, and is, of course, blind to the ultraviolet which is so active photochemically. Many chemical photometers, or actinometers as they are called, have been invented, but all of them have the same fault in that they are not equally sensitive to light of all wave-lengths. Ignorance of this fact has rendered of little value much of the early work in photochemistry.

One of the instruments most used for measuring light intensity in modern photochemical research is the thermopile. This instrument is based on the well-known fact that when radiant energy falls upon a junction between two different metals, that part of the energy which is absorbed heats the junction and will cause a current of electricity to flow from the one metal to the other through an external circuit. If a delicate galvanometer be included in the circuit, the current may be measured, and by comparing this current with that produced by a radiation of known intensity, the total radiation from any source may be measured. The radiation of known intensity is obtained from a so-called "black-body" radiator. Stefan discovered empirically, and Boltzmann derived by thermodynamic reasoning the law now known as the Stefan-Boltzmann law, which states that the total radiation from a perfectly black body is proportional to the fourth power of the absolute temperature. Stated algebraically $S = CT^4$, where S is the total radiation, T the absolute temperature, and C a natural constant having a value approximating 1.71×10^{-8} ergs per square centimeter per second. It is, of course, not possible to construct a "perfectly black body," in the sense here used, but the deviation of certain actual radiators from the ideal is negligible.

Another instrument often used to measure radiant energy is the radiomicrometer. In this instrument a thermopile and small circuit are suspended by a fine fiber between the poles of a magnet. When light falls upon the thermopile, a small electrical current flows through the circuit and the suspended system is turned by the magnetic field as in the D'Arsonval galvanometer, the effect being magnified by an optical lever.

Types of Photochemical Reactions

In general it may be said that light is capable of bringing about every type of chemical reaction. The number of photochemical reactions now known is far too large to allow a consideration of each one individually. We shall, therefore, only point out a few examples under each type of reaction.

Oxidation Reactions.

a. Lead sulphide is oxidized to lead sulphate by light and air:

b. Sulphur dioxide is partially oxidized to sulphur trioxide by light and oxygen:

Reduction Reactions.

Silver salts, iron salts, mercury salts, bismuth salts, etc., are reduced by light, the metal being liberated in some cases, in others a salt corresponding to a lower valence of the metal being formed. The ordinary process of blue-printing involves the photoreduction of an iron salt.

Polymerization.

a. Under the influence of light oxygen is converted partially into ozone, the equilibrium between the oxygen and the ozone depending upon the temperature and the intensity of the light used.

b. In organic chemistry a great many polymerizations have been accomplished by means of light. As a simple example we may cite the conversion of cyanogen into paracyanogen:

Depolymerization.

Ozone is partially decomposed into oxygen, the decomposition proceeding until the equilibrium point has been reached as in the formation of ozone from oxygen.

Allotropic Changes of the Elements.

Under the influence of light sulphur which is soluble in carbon disulphide, so-called S_λ , is converted into sulphur which is insoluble in carbon disulphide, so-called S_μ .

Likewise yellow phosphorus is converted into the red modification at a very much higher rate than occurs in the dark.

Isomeric Changes.

Light is especially active in bringing about isomeric changes in organic chemistry. For example, maleic acid becomes fumaric acid under the influence of light, ortho-nitrobenzaldehyde becomes ortho-nitrobenzoic acid, isocrotonic acid becomes crotonic acid, cumaric acid becomes coumarin, etc.

Light may also bring about stereo-isomeric changes, as, for example, in nearly all the fulgides, where the change is usually accompanied by a change in color.

Hydrolysis.

Hydrolyses, especially in organic chemistry, are readily accomplished by light. Thus acetone and water react to form acetic acid and methane:

Ethyl bromide yields alcohol and hydrobromic acid:

Synthesis.

a. Hydrogen and chlorine combine to form hydrogen chloride with explosive rapidity in direct sunlight:

b. Carbon monoxide and chlorine combine to form phosgene:

c. In organic chemistry a great many syntheses have been carried out by means of light, this method often affording a direct and simple means of carrying out reactions which may be accomplished only with much difficulty by other means.

It has long been known that the halogenation of organic compounds is much hastened by exposing the reaction mixture to sunlight. In this connection it is interesting to note that a close parallelism exists between halogenation at high temperatures and halogenation in sunlight.

Decompositions.

a. Light decomposes hydrogen iodide very readily in the presence of oxygen or air:

b. Hydrogen peroxide is decomposed into water and oxygen:

The rate of decomposition is greatly influenced by the presence of a trace of foreign substance in the solution, in most cases the solution becoming more stable upon the addition of the foreign substance.

c. Under the influence of light of short wave-length, most organic compounds are decomposed into simpler substances. In Table III are given the decomposition products of a number of simple organic compounds.

TABLE III—DECOMPOSITION PRODUCTS OF ORGANIC COMPOUNDS

Compound	PERCENTAGE OF PRODUCTS					
	CO ₂	CO	H ₂	CH ₄	C ₂ H ₆	C ₂ H ₁₀

A Few Unsolved Problems of Photochemistry

I. THE CHLOROPHYLL PROBLEM

Chemical action may easily be caused to produce light; indeed artificial light was produced in no other way until modern times. To drive chemical actions by means of light is, however, a process about which but little is known, although it is a process which every growing plant successfully accomplishes.

The photochemistry of plant assimilation is now receiving much attention. In this process, carbon dioxide and water are the raw materials, carbohydrates the chief of the finished products. Between these two systems, carbon dioxide plus water on the one hand, and carbohydrates on the other, is a big gap in energy which the plant crosses by utilizing the energy of sunlight. The active agent in this transfer, the chief engineer if you please, is a certain green substance called chlorophyll, but beyond the fact that the goods are delivered on the proper side of the gap, not much is known about the process.

It is possible to manufacture carbohydrates from water and carbon dioxide in the laboratory. It is even possible to do this by means of light without the aid of chlorophyll. Here, however, an unfair advantage must be taken by using light of shorter waves than occur in sunlight. It seems probable that chlorophyll plays the part of a photocatalyst, by the aid of which plant assimilation may proceed in light of much lower waves than could otherwise be utilized. There are other examples of such photocatalysis or "optical sensitization," of which a familiar one is the use of certain dyes to extend the sensitiveness of the photographic plate into the yellow and red region of the spectrum.

In recent years much progress has been made by Professor Willstätter and his students toward solving the "chlorophyll problem" but much remains unknown about this photochemical process to which all the coal beds on earth owe their origin. Could we but learn to "speed up" the process of plant assimilation, as we can speed

up the process of combustion, sun-power would certainly become a factor in the industrial world.

II. THE LAWS OF PHOTOCHEMISTRY

A study of the kinetics of photochemical reactions is complicated by a number of troublesome factors, and progress in this line has been slow.

In order to be photochemically active, light must be absorbed. The fact of light absorption by a system, however, does not necessitate chemical action, since the light absorbed may be converted into heat. When photochemical action does occur, the degree of absorption is an important factor in determining the mechanics of the reaction. It appears that in reversible reactions with a large absorption of light, the velocity of the reaction becomes simply proportional to the amount of light absorbed per unit time, which is obviously a law analogous to the Faraday law of electrolysis. With an irreversible reaction having a small absorption, however, the mass law may be applied with a few modifications.

But little is known about the catalysis of photochemical reactions, which is not surprising in view of our almost complete ignorance as to the nature of catalysis in general.

The effect of temperature on photochemical reactions is much smaller than on other reactions. An increase of temperature of 10 deg. will usually double or treble the rate of an ordinary reaction, while the same increase of temperature seldom multiplies the rate of a photochemical reaction by more than one and a half, and in many cases has very little effect at all. It is well known, for example, that a photographic plate is nearly as sensitive at the temperature of liquid air as it is at ordinary temperatures.

The whole subject of photochemical kinetics is, as yet, much confused, and a great deal of quantitative experimental data are needed. There is undoubtedly some relationship between the chemical reactivity of a substance under influence of light and its molecular structure, just as there must be between its color, itself a photochemical phenomenon, and its molecular structure.

III. COLD LIGHT

The total energy radiated by a body is proportional to the fourth power of its absolute temperature (Stefan-Boltzmann law). This energy, however, is not evenly distributed in the spectrum, but for each temperature there is a characteristic distribution curve having a maximum at a certain wave length. As the temperature is raised, this maximum shifts toward the region of shorter waves. We are all aware of the qualitative operation of this law, that when the temperature of a body is gradually raised, heat waves are at first emitted, and later light waves of the longest wave length visible, i.e., red light. Obviously all "perfectly black bodies," i.e. such as follow the Stefan-Boltzmann law, would grow "red hot" at one definite temperature, while actual bodies, which differ somewhat from the ideal black body, will become red hot at temperatures which differ somewhat, but are not far from that of the ideal black body. All incandescent lamps operate on this principle, and the radiations produced are by no means limited to the visible regions of the spectrum, so that a considerable portion of the electrical or chemical energy used in the operation is wasted so far as the production of light is concerned.

So much for the ordinary emission of light. There are many cases known, however, where light is emitted from a body whose general temperature is far below red heat. Several kinds of luminescent bacteria are known; the fire-fly and glow-worm are common; phos-

phorus glows when exposed to air and moisture; fluorite emits a bluish-green light when gently warmed; certain sulphides will glow in the dark after a preliminary exposure to light; many chemical reactions are accompanied by the production of light at ordinary temperatures; crystallization is often accompanied by tiny flashes of light, and a similar phenomenon is to be observed when certain crystals are crushed.

In all these cases the light is produced at temperatures which are several hundreds of degrees below that which would be required by the ordinary laws of radiation. This phenomenon, the production of "cold light" by any of the above-named means, goes under the general name of luminescence. The mechanism of the process or processes is unknown.

That all forms of energy are mutually and quantitatively interconvertible is one of the axioms of physical science. The practical problem of converting one form into another is, however, a problem of gigantic proportions, one which has claimed the attention of men from earliest times. That the problem has in part been solved, is evidenced by the tremendous operations of modern industry. It is perhaps not too much to say that modern civilization could not have been attained had man not learned to transmute energy. There is, however, little room for pride in the achievement, for at every transfer much of the valuable free energy is spilled into the great dead-level ocean of heat to which every form of energy seems destined to revert ultimately. Engineers talk much of "efficiency" and seem to feel that the word lends a luster of achievement to their discourse. The real fact is that the word "efficiency" hides the chagrin with which they deliver at its destination so small a fraction of the total amount of energy which they bravely essayed to transform.

It so happens that some of the transformations are much easier to make than others; mechanical energy may be transformed into electrical energy, and vice versa, with but little loss, while in the transformation of heat energy into mechanical energy but little is saved. Among those transformations in which least skill is shown is the production of light. If produced through the chemical process of combustion, but a small part of the chemical energy liberated becomes light; the various electric incandescent lamps do better, but even here a considerable portion of the electrical energy is spent in producing waves of radiant energy far too long to be seen. To transmute chemical energy wholly into visible radiant energy is a problem which has so far utterly defied practical solution. The photochemist is still struggling with the problem. If therefore he is discovered hovering about some swampy place with a fine-mesh butterfly net, be sure that he is only pursuing common fire-bugs, although the results so far achieved in this line would indicate that he has captured only will-o'-the-wisps.

Coal and Coke in Canada.—The production of coal and coke in Canada during 1914 is the subject of an advance chapter of the annual report of the mineral production of Canada by the Department of Mines.

Removal of Logwood Embargo in Jamaica.—According to a telegram from the American Consulate at Kingston to the Department of Commerce, the embargo on logwood, logwood chips and logwood extract, including hematin crystals and other logwood preparations, has been raised.

The copper-nickel mattes produced by the Canadian Canadian Copper Co. and the Mond Nickel Co. in Canada are shipped respectively to New Jersey and to Wales for refining. Gold, silver, platinum and palladium are recovered as by-products from this matte.

Refrigeration in France*

BY L. MARCHIS

I—The Technique of Very Low Temperatures

The industrial production of liquid air, of oxygen, of nitrogen and of hydrogen, have, thanks to the labors of G. Claude, made great progress during the last few years. We shall here give in résumé the more important results of his researches.

1. PRODUCTION OF LIQUID AIR

Claude utilizes the external work produced by the passage of air from a high to a lower pressure, but he applies this well-known method in the following manner for the production of low temperatures.

The air compressed to a maximum pressure of 40 atmospheres, passes into a cooler where its temperature is reduced as we shall see at a later point.

This current of air, cooled and compressed to 40 atmospheres, is then to be passed into a cylinder where work is produced by expansive action on a piston. But before reaching this expansion cylinder, a part of the air is diverted from the main conduit. This diverted air, at a pressure of 40 atmospheres, reaches a cooled inclosure (liquefier) where the air is liquefied at the temperature of -140 deg. C. The remainder of the air (from which the portion has been diverted) then passes on to undergo an expansion by stages in a series of cylinders within which are pistons on which the air acts with the production of work.

The air, exhausted after the first expansion, is circulated about a first liquefier traversed by the diverted air (referred to above) at 40 atmospheres pressure. This air, which has undergone a first expansion, is warmed and then expanded in a second auxiliary cylinder. The air of the second expansion is sent into a second liquefier similar to the first.

Finally this air, twice expanded, is caused to circulate in the cooler where it operates as a cooling agent for the air compressed to 40 atmospheres which comes from the compressor.

For machines using a compressor of 75 hp., the delivery of liquid air is equal to 0.85 liter (0.224 gal.) per effective horsepower-hour.

2. SEPARATION OF THE OXYGEN AND NITROGEN OF THE AIR

Liquid air is especially important because it tends to become the only industrial source of oxygen and of nitrogen. The production, at a low price, of these two gases is a problem, the solution of which is of great importance for metallurgy and for the fertilizer industry. How may these two gases be derived from liquid air? This problem we shall now proceed to examine.

Oxygen and nitrogen are two substances of which the critical points are distinctly different, as follows:

— 119 deg. C. and 51 atmospheres for oxygen.

— 146 deg. C. and 34 atmospheres for nitrogen.

If, in the plane POT (OP vapor pressure ordinates; OT temperature abscissæ) we trace the curve of vapor tension for the saturated vapors of oxygen and of nitrogen, it will be found that the curve for nitrogen will lie above that for oxygen. At the same temperature, lying below the critical temperature, nitrogen is liquefied under a pressure higher than oxygen; at the same pressure, inferior to the critical pressure of the two gases, nitrogen is liquefied at a temperature lower than oxygen. Thus under atmospheric pressure oxygen is liquefied at -182.6 deg. C. and nitrogen at -194.4 deg. C.

3. SPECIAL CIRCUMSTANCES PRESENTED BY THE LIQUEFACTION OF AIR (MIXTURE OF OXYGEN AND NITROGEN)

The liquefaction of air, that is of the mixture of the two gases oxygen and nitrogen, presents certain special conditions which we must here note.

If, at a constant temperature T , sufficiently low, air is compressed in a closed chamber, the following phenomena are observed:

(1) At a certain value P_0 of the pressure, there appears the first drop of liquid; we shall designate the state of equilibrium characterized by the value P_0T by the term "dew-point."* For all pressures less than P_0 , the air is in the state of homogeneous vapor; from P_0 upward, separation of the air in two phases is produced.

(2) If, at the constant temperature T , the volume of the air is continuously decreased, the pressure rises; at the same time the amount of the liquid phase increases and the amount of the vapor phase decreases. If the increase in pressure is continued, the air passes entirely into the liquid state; the values P_0 and T of the pressure and of the temperature at this instant characterize what we shall term the "boiling-point."

For all pressures exceeding P_0 , the air is in the state of homogeneous liquid; for all pressures comprised between P_0 and P_0 , the air is divided into two phases, one liquid and one vapor.

(3) The "dew-points" and the "boiling-points," obtained at diverse temperatures trace in the plane POT (OP , ordinates; OT , abscissæ) on the one hand the line of dew and on the other the line of ebullition of the gaseous mixture considered.

The line of ebullition lies entirely above the line of dew; the two lines come together at the critical point, that is, in the present case, at the point for which the co-ordinates are 39 atmospheres and -140 deg. C.

(4) For each system of values (TP) of the temperature and of the pressure (T below the critical temperature and P lying between P_0 and P_c), there exists a state of equilibrium of the combination of the two phases in contact one with the other. In this state the compositions of the two phases are different.

(5) Let us apply the term "oxygen quality" of the phases, liquid and gaseous, to the percentage of oxygen (the more liquefiable element) in each of them.

The oxygen quality of the liquid phase is, in the state of equilibrium, always higher than that of the gaseous phase. The liquid is always richer in oxygen than the vapor.

When, at constant temperature the pressure rises, the oxygen qualities of the phases, liquid and gaseous, continuously decrease to the complete liquefaction of the mixture.

4. THE SEPARATION OF OXYGEN AND NITROGEN CAN NOT BE REALIZED WHEN, IN THE LIQUEFACTION OF AIR, THE LIQUID AND GASEOUS PHASES ARE MAINTAINED IN CONTACT

Thus when air is liquefied (volumetric content 21 per cent of oxygen) the first drop of liquid which is formed contains both oxygen and nitrogen and its "oxygen quality" is 47 per cent. The values of the "oxygen quality" continuously decrease in proportion as the volume of the liquid phase increases: It is thus that liquid at 34 per cent can only be in equilibrium with vapor at 12.5 per cent. But, so long as a gaseous phase exists, its oxygen quality is very different from 0; it remains greater than 7 per cent.

If the two phases, liquid and gaseous, obtained by the progressive liquefaction of air are maintained in con-

*A paper read before the International Engineering Congress in San Francisco.

*Note that this is entirely distinct from the dewpoint relating to water vapor and air. (T.V.)

tact, it is impossible to prepare gaseous nitrogen free of oxygen, that is with a sufficient degree of purity.

5. DISTILLATION OF LIQUID AIR UNDER CONSTANT PRESSURE

It is not the same, however, when, maintaining the pressure constant, the liquid phase is removed as rapidly as formed. In such case the phenomenon encountered is the inverse of that met with when liquid air is distilled under constant pressure. In this case the oxygen qualities of the phases, liquid and gaseous, continuously increase; these phases, separated one from the other as rapidly as formed, tend toward a content of pure oxygen; at the same time the temperature of ebullition rises from a value nearly that of pure nitrogen to the temperature of ebullition of pure oxygen.

6. CONDENSATION OF AIR UNDER CONSTANT PRESSURE WITH ELIMINATION OF THE LIQUID PHASE

Inversely, if, under constant pressure, air is progressively condensed, removing the liquid phase as rapidly as formed, liquids and gaseous residues are obtained less and less rich in oxygen; at the same time the temperature of condensation drops and tends toward the temperature of ebullition of pure nitrogen under the pressure considered. There is thus obtained a gaseous mixture richer in nitrogen than that obtained by leaving the liquid and gaseous phases in contact.

However, in order to obtain a gaseous residue sensibly free of oxygen, it is necessary in this method to liquefy practically all of the air.

7. THE COUNTER-FLOW METHOD OF G. CLAUDE

A better result is realized by the use of the method designed by Mr. Claude under the name of regenerative or "counter-flow" method.

Let us assume in any case the progressive condensation of the air and the removal of the liquid phase as rapidly as formed. But assume further that the liquid thus obtained meets, in separating from the gas, a gaseous mass richer in oxygen. The liquid is colder, as a consequence of the high percentage of nitrogen which it contains; a part of the more condensable oxygen of the gaseous mixture will then become liquid and will take the place of the nitrogen which is vaporized. Thus by a counter-flow circulation of the liquid and the gas of different oxygen qualities, there is obtained, on the one hand, a liquid very rich in oxygen, and on the other, *gaseous nitrogen practically pure*. The latter comes, furthermore, in large part from air treated but not liquefied.

Mr. Claude has realized as follows the principle of the "counter-flow":

A form of small tubular boiler is disposed in such manner that its axis is vertical. The tubes are surrounded on the outside by the liquid air. There is then passed into the inside at the bottom a current of cold compressed air. This in passing up through the tubes is progressively liquefied, producing both liquids and vapors less and less rich in oxygen. The vapors continue to rise toward the top of the tubes while the condensed liquid descends toward the bottom. This liquid, in falling into the lower receptacle, meets the gaseous portions rich in oxygen, and thus is produced the continuous exhaustion, of which the principle has been set forth above. There is thus liberated from the top of the nest of tubes practically pure nitrogen, while liquid specially rich in oxygen is continuously drawn from the bottom.

8. THE PREPARATION OF PURE OXYGEN AND OF NITROGEN 97 PER CENT OR 98 PER CENT PURE

A second stage remains to be realized. Instead of air with an oxygen content (volumetric) of 47 per cent., it is required to obtain oxygen practically pure. This is

realized by means of methods of *rectification* based on those employed in the manufacture of alcohol.

In a vertical column there circulate: (1) From bottom to top, oxygen vapor practically pure; (2) from top to bottom, liquid with a high percentage of nitrogen. The latter, colder, condenses the oxygen and allows its nitrogen to escape in the gaseous condition, according to the procedure above developed in the description of the counter-flow method.

The apparatus is composed of a sort of tubular boiler with axis vertical. This is extended on top by a sheet-metal cylinder of the type employed in the distillation of alcohol. The vertical tubes of the boiler are surrounded by liquid oxygen practically pure. On the inside and at the base of the tubes, air is led in under a pressure of 5 atmospheres. As has been explained above, this air is liquefied, giving a liquid air with excess of oxygen in the lower part of the tubes and nearly pure gaseous nitrogen in the upper part. The latter is carried through the liquid oxygen and is liquefied in turn. In consequence of its pressure, the liquid with excess of oxygen flows out continuously at the middle part of the rectifying column, while the liquid nitrogen, very poor in oxygen, overflows at the top of the column.

Furthermore, the oxygen which surrounds the boiler is vaporized, as a result of the disengagement of heat resulting from the condensation of the air in the interior of the tubes. This vapor of oxygen, in rising through the column, encounters liquids richer and richer in nitrogen. It is then condensed, taking the place of the nitrogen which is vaporized. Thus practically pure liquid oxygen falls back into the boiler, while pure nitrogen is liberated at the upper part of the rectifying column. The mass of liquid oxygen which falls back into the boiler is superior to that which is vaporized in rising through the column. The excess of oxygen is evacuated and carried through a cooler to the gasometer or point of utilization. This cooler serves to cool the air at 5 atmospheres pressure which is introduced into the base of the apparatus.

The ensemble of this equipment (cooler, liquefier, rectifying column) is surrounded by a thick layer of heat insulating material which opposes the inflow of heat.

The delivery of this apparatus is approximately 1 cu. m. (35.3 cu. ft.) of pure oxygen per effective horsepower-hour for the size producing 50 cu. m. (1765.7 cu. ft.) per hour; 1.2 cu. m. (42.4 cu. ft.) for the sizes producing 100 to 200 cu. m. (3530-7063 cu. ft.) per hour; 1.5 cu. ft. (53 cu. ft.) for the sizes producing 1000 cu. m. (35,300 cu. ft.) per hour, operating at pressures of 10 atmospheres at the most. For these latter, aside from the motive power, the costs (labor and fixed charges) will not exceed 0.01 franc per cubic meter of oxygen (0.005 cent per cubic foot). With the motive power available in the neighborhood of furnaces and waterfalls, the total cost of oxygen will result, according to Mr. Claude, about 0.02 franc per cubic meter (0.01 cent per cubic foot) or 15 francs per ton (density of liquid oxygen 1.33) (\$2.62 per ton of 2000 lb.)

At the present time the forty plants which are operating with the preceding apparatus (Liquid Air Company) are producing annually 24,000,000 cu. m. (847,000,000 cu. ft.) of liquid oxygen. Operating at the same time, they would furnish 3000 cu. m. (105,900 cu. ft.) of oxygen per hour while liquefying 40 tons of air per hour. The factory at Boulogne-sur-Seine operates with two units each of 150 cu. m. (5300 cu. ft.) capacity.

9. THE PREPARATION OF NITROGEN WITH 0.2 PER CENT OXYGEN

Nitrogen with 2 per cent or 3 per cent of oxygen, the preparation of which we have just described, cannot be employed in the manufacture of cyanamide.

In improving the method of rectification described above Mr. Claude has succeeded in preparing nitrogen containing not more than 0.2 per cent of oxygen (called nitrogen 99.8 per cent pure).

The principal fault of the apparatus for the production of pure oxygen consists in its insufficient production of liquid nitrogen. The residual gases coming from the progressive condensation of the air do not find, in passing again through the bath of oxygen, a medium sufficiently cold to completely condense them, but in the rectifying column there may be found a part sufficiently cold to secure the more complete liquefaction of the nitrogen resulting from the progressive liquefaction of the air.

It is for this reason that in the new equipment constructed by Mr. Claude the residual gases coming from the progressive liquefaction of the air, instead of passing into the liquid oxygen, are conducted through a serpentine liquefier placed in a sufficiently cold region of the rectifying column. Nitrogen, liquefied in this region, is led to the upper part of the rectifying column and flows from above downward, meeting the vapors of oxygen coming from the bath which surrounds the lower liquefier.

At the present time the Liquid Air Company, which is exploiting the processes of Mr. Claude, has in operation or under construction 18 units for pure nitrogen, each of 500 cu. m. (17,650 cu. ft.) capacity per hour. When they are all in operation at the same time, 3 tons of nitrogen per hour may be delivered.

10. THE PREPARATION OF HYDROGEN

Hydrogen is extracted from water gas. It is known that this gas contains on the average 50 per cent of hydrogen and 40 per cent of carbon monoxide. The separation of these gases is very readily made by the methods of Mr. Claude. However, the process has not as yet been carried to the point of industrial production. The Liquid Air Company is making experiments in this direction and is liquefying 150 to 200 kg. (330 to 440 lb.) of carbon monoxide per hour. This substance may be employed mixed with oxygen to form an explosive mixture available as fuel in an internal combustion engine.

11. THE EXTRACTION OF THE RARE GASES IN THE ATMOSPHERE

The counter-flow method of Mr. Claude has made possible the extraction from atmospheric air of the rare gases, helium, neon, argon, krypton and xenon. It secures, in fact, the possibility of gathering, as a by-product of the industrial manufacture of oxygen and of nitrogen, a mixture of nitrogen and at the least 50 per cent of rare gases, and more particularly of neon and helium.

To this end, the gaseous residues which are the most difficult of liquefaction are led, in the proportion of 6000 liters (1585 gal.) per hour for a delivery of air of 3500 cu. m. (123,500 cu. ft.), to the lower part of a tubular system cooled by liquid nitrogen. Under the simultaneous effect of the pressure of 4 atmospheres and of the very low temperature, the condensation of all liquefiable substances results.

The gaseous residue is constituted, if the delivery is properly regulated, of a mixture almost pure of neon and helium. An apparatus of a capacity of 50 cu. m. (1765 cu. ft.) oxygen per hour produces per day 100 liters (26.4 gal.) of neon or 30 cu. m. (1059.4 cu. ft.) per year.

Neon is now employed in tubes which light up with a rose color as a result of the passage of an electric current at high voltage. These lamps give approximately 200 cp. per running meter of tube and require about 0.6 watt-hour per candle power. By the intro-

duction of a little mercury into the neon tubes, a beautiful blue light is obtained.

12. LIQUID OXYGEN EMPLOYED AS AN EXPLOSIVE

Liquid oxygen may serve as an explosive. Cartridges composed of ordinary lampblack, dipped for a few moments in a bucket filled with liquid oxygen and primed with a fulminate cap, constitute a formidable explosive, as powerful as gum dynamite and costing only one-fourth to one-fifth as much as the latter.

13. PRODUCTION OF TEMPERATURES DOWN TO — 211 DEG. C. BY THE USE OF LIQUID NITROGEN

Hydrogen boils under atmospheric pressure at a temperature of — 252.6 deg., but this substance is still difficult to procure in considerable quantity. Mr. Claude has indicated a simple method for obtaining in a few minutes a temperature of — 211 deg. when liquid nitrogen is available. This process is more convenient, more rapid, and permits of operating with a restricted equipment, on quantities of liquid nitrogen greater than by means of evaporation under partial vacuum.

When there is passed into a liquefied gas a rapid current of air, the liquid is cooled very much below its normal point of ebullition.

The liquid nitrogen is placed in a Dewar-d'Arsonval tube freely open to the air. There is first passed in a rapid gaseous current of hydrogen, first cooled in liquid nitrogen. In the experiment, the rapidity of the current of hydrogen is gradually raised from 20 to 25 liters (5.3 to 6.3 gal.) per minute to 50 or 60 liters (13.2 to 15.85 gal.) per minute.

Under these conditions, a period of about twelve minutes is sufficient in order to lower the temperature of the liquid nitrogen to — 210 deg. C. From this point on, the temperature remains sensibly fixed. After twenty minutes, a temperature — 211 deg. is reached; a limiting temperature corresponding to the slow congelation of nitrogen. There may be thus realized a fixed point in a manner quite as convenient as those of the boiling points of oxygen and of nitrogen.

One might employ the same general method with liquid oxygen, but in this case the limiting lower temperature would be — 204 deg. In order to obtain with this substance the same temperature by a reduction of pressure, it would be necessary to boil it under 50 mm. (1.9685 in.) of mercury.

14. RECOVERY OF VOLATILE LIQUIDS. METHOD OF MR. CLAUDE

In several important industries (artificial silk of Chardonnet; smokeless powder; celluloid, etc.) costly liquids are frequently lost (alcohol and ether in particular) under the form of vapors diluted in enormous masses of air. Often, even in spite of a very considerable recovery, these losses in certain establishments may reach millions of francs per year.

Mr. Claude has proposed for this recovery a method which presents analogies with those which we have previously noted.

I—Air charged with water vapor and with vapors of alcohol and ether is compressed to a pressure such that it is sensibly saturated with water vapor at the temperature which it possesses at the end of compression, and in consequence, such that it will be saturated with water vapor after reaching its ordinary temperature. To realize this result, a pressure of 4 to 6 atmospheres is practically sufficient.

II—The compressed air is cooled in a refrigerator using water. As a result of its super-saturation with regard to the vapor of water, the latter condenses, carrying with it a little alcohol and other vapors, notably vapors of camphor (celluloid industry).

III—The compressed air, relieved of the larger part of its vapor of water, is then carried to the "recoverer." This is a sort of vertical tubular boiler. The compressed air rises from the bottom to the top through the interior of the bundle of tubes. A counter current of cooled air arrives on top of the "recoverer" and circulates from above downward around the bundle of tubes. The compressed air, in rising, meets with air colder and colder. On entering the bundle of tubes, the compressed air condenses out a mixture of water and alcohol. As this mixture can only be solidified at a temperature considerably below zero, there is no danger of an obstruction of the tubes by the solidification of the water. In proportion as the compressed air rises in the bundle of tubes, it deposits mixtures of water richer and richer in alcohol and in ether, that is to say, less and less readily congealed. These mixtures, flowing from above downward in the bundle of tubes, come into contact with regions continuously warmer. The danger of obstruction by ice is then less and less to be feared.

When the compressed air first arrives at the top of the "recoverer," or transformer, it may be subject to a temperature as low as -90 deg. C., a temperature at which the maximum tension of the vapor of ether is less than 0.5 mm. (0.0197 in.), but which is insufficient to congeal it. The collection of vapors accumulates in the liquid state in the lower receptacle, while the compressed air escapes from the top of the apparatus completely deprived of its vapors.

IV—This compressed air, exhausted of its vapors and cooled, is then carried to the cylinder of an engine where it expands with the production of work. This expansion produces a further marked reduction of temperature in the air. It is this air, at a temperature of -120 deg. to -130 deg., which, passed from above downward in the apparatus as a counter current in opposite direction to the compressed air, determines the program of descending temperature of which we have just analyzed the consequences.

V—It is preferable in the apparatus to push the refrigeration to the point where alcohol alone is separated. The ether is then in the way of separation disseminated in the air in the form of small globules. Carried along by the current of air from the bundle of tubes, it is then separated mechanically by its passage through a separator provided with pierced baffles.

VI—The following is a method of operation of the apparatus with regard to the production of low temperatures:

At the beginning all parts of the apparatus being at the same temperature, there is at first in the compressor a warming of air and a disengagement of heat which is absorbed by the circulating water. The compressed air enters the bundle of tubes in the apparatus at ordinary temperature, whence it flows out sensibly at the same temperature. The temperature of this air then becomes lowered in the expansion prime mover. This expanded air returns, chilled, into the shell of the apparatus; there it is warmed before escaping, but it cools the compressed air traversing the tubes. This air then enters the expansion prime mover at a reduced temperature, whence it issues, still colder and with capacity for still further cooling of the compressed air in the bundle of tubes, and so on from one round to another with reducing temperatures.

About one-half hour is required for the realization of the condensation.

With large units, where the initial compression need not exceed 4 kg. per square centimeter (56.89 lb. per square inch), as much as 16 cu. m. (565 cu. ft.) of air may be treated per horsepower-hour.

The Lyons Celluloid Company has made in its Oyonnax factory an installation for treating 200 cu. m. (7063 cu. ft.) of air coming from the laminators and dryers of celluloid. This air, aside from water vapor, is charged with vapors of camphor, alcohol and ether. The apparatus driven by a 25 -hp., three-phase motor, giving an initial compression of 5 atmospheres, secures the recovery each twenty-four hours of 150 kg. (330 lb.) of alcohol, 80 kg. (176 lb.) of ether, and 15 kg. (33 lb.) of camphor. In the expansion prime mover the temperatures are: At admission, -60 deg. C. and at exhaust -110 deg. C.

There is no danger of explosion. A warm explosive mixture with dry air and ether is not produced until the proportion of ether reaches 50 to 60 grams per cubic meter (0.0021 - 0.0037 lb. per cubic foot), but in these cases the mixture contains vapor of water and about 20 grams of ether per cubic meter (0.0012 lb. per cubic foot). Furthermore, the mixture is cooled in issuing from the compressor.

II.—Heat Insulators

Fourier's theory of the conduction of heat leads to the following propositions:

1. If a substance has two infinite plane parallel boundary faces, the quantity of heat which, under steady conditions, flows across a surface S from one of these boundary faces to the other is given by the equation:

$$Q = kS \frac{T_1 - T_2}{l} t \quad (1)$$

where Q = quantity of heat, S = area, l = distance between the two surfaces, T_1 , T_2 = temperatures of the two faces, t = time, k = coefficient of internal conduction of heat (thermal conductivity) for the substance.

2. Let us consider two media exterior to the substance under consideration and touching the boundary surfaces of this substance. In these media let us trace two planes parallel to the boundary surfaces of the substance and infinitely near to them. Let us call Θ_1 and Θ_2 the temperatures on these planes in the media which are in contact with the boundary surfaces of the substance under examination. If we consider an area S on these planes at temperatures Θ_1 and Θ_2 , we may, as soon as steady conditions are established, write the following relations:

$$Q = a_1 S (\Theta_1 - T_1) t = kS \frac{T_1 - T_2}{l} t = a_2 S (T_2 - \Theta_2) t \quad (2)$$

$$\left. \begin{aligned} \Theta_1 - T_1 &= \frac{Q}{St} \times \frac{1}{a_1} \\ T_1 - T_2 &= \frac{Q}{St} \times \frac{l}{k} \\ T_2 - \Theta_2 &= \frac{Q}{St} \times \frac{1}{a_2} \end{aligned} \right\} \quad (3)$$

Whence adding and solving for Q we find

$$Q = KS (\Theta_1 - \Theta_2) t \quad (4)$$

in which

$$\frac{1}{K} = \frac{1}{a_1} + \frac{l}{k} + \frac{1}{a_2} \quad (5)$$

K is the coefficient of transmission of heat from the one of the media at temperature Θ_1 to the other at temperature Θ_2 through the substance of thickness l . It is a coefficient of special importance in the refrigerating industry.

Mr. Biquard of the Conservatoire des Arts et Métiers, at Paris, has studied the various factors on which this coefficient depends.

He gives to the coefficient $\frac{1}{a_1} + \frac{1}{a_2}$ the name "insulating value" due to the boundary surfaces. If the conditions on the two surfaces are the same,

$$a_1 = a_2 \text{ and} \\ \frac{1}{a_1} + \frac{1}{a_2} = \frac{2}{a}$$

To the coefficient 1 K Mr. Biquard gives the name *overall insulating value*.

It is of interest to examine the influence of the boundary surface of the substance. This influence is only negligible when the values of 1 K are greater than 4. In this case the "insulating value" of the boundary surfaces is scarcely 5 per cent of the overall value. The latter is in such cases proportional to the thickness of the substance, the coefficient of proportionality k being the reciprocal of the thermal conductivity.

3. The experimental determination of this last coefficient is then of very great importance. Mr. Biquard has made his determinations in realizing, as far as possible, the conditions of Fourier's definition.

To this end he employs the method known in experimental physics under the name of the "guard-ring method."

Let us suppose that in a large plate of insulating substance (flat with parallel faces) we isolate, in thought, a cylinder of section S situated at a great distance from the rims of the plate. Let us assume that, without changing anything in the mode of propagation of heat in the ensemble, we measure the quantity which, under steady conditions, passes from one of these faces to the other of the cylinder of section S . Everything will happen as though the substance studied had infinite parallel faces. The propagation of heat in the cylinder of section S will not be modified by the presence of the sections surrounding it. In this manner, in the experiment, the conditions of the theory will have been realized. The part of the substance which surrounds the cylinder of section S is the guard ring. The breadth of the latter outside the cylinder of section S should be equal to about twice the diameter of this section.

Mr. Biquard has thus realized these conditions:

The insulating substance under examination is placed between two plates of copper maintained, one at 0 deg. C. by melting ice, the other at a temperature constant and definitely determined by means of a current of water. The ice is placed in two chambers separated by an insulating partition; one of these chambers corresponds to the cylinder of section S , the other to the guard ring. The plate of copper which is in contact with the ice, shows, furthermore, a groove limiting the cylinder of section S . The quantity of ice melted in a given time in the chamber which corresponds to the section S is then measured.

We give some of the results found by Mr. Biquard:

1. The smallest coefficient* of internal heat conduction seems to be that of Javanese kapock packed to weigh 15.7 kg. per cubic meter (0.97 lb. per cubic foot).

2. The coefficient of internal heat conduction of a heat insulator increases considerably when it has absorbed humidity. If one takes, for example, granulated cork mixed with tar, its coefficient of internal conduction equals 0.052 when the substance is dry (packed to weigh 275 kg. per cubic meter [17.1 lb. per cubic foot]). This coefficient becomes equal to 0.076 after a period of twenty days soaking in water, as a result of which the cork takes up 310 kg. of water per cubic meter (19.3 lb. per cubic foot) by way of absorption.

*In the advance copy of the paper from which this is reprinted, this value is given as "0.034 meter, calories-Kil-log, hour, per deg. Cent." It is not clear what unit is meant. If it means kilogram-calories flowing per hour through a section of 1 sq. meter for a thickness of 1 meter of the insulating material, this and the following figures do not seem to check with published figures at all. We trust that this will be cleared up in time. But as for the purpose of this paper the relative values only of the heat conductivities are of interest, the absolute values are of less importance.—Editor.

3. Insulators with intervals of air can only be employed when they can be maintained dry and the air quiet. In such case the most suitable thickness for the layers of air is comprised between 8 and 25 mm. (0.315 to 0.984 in.). If such layers of air are employed, it is indispensable to reduce to a minimum the thickness of solid matter, in directions both parallel and perpendicular to the walls.

From this viewpoint, the "fibrous cement" which, under a thickness of a few millimeters, present a satisfactory mechanical strength, seems likely to give good results.

The Grading Industries—II

BY EDWARD S. WIARD

(Continued from page 96)

Screens and Screening

The splitting of loose fragmental or granular material into three or more sizes and according to one or two linear dimensions of an opening, which is commonly called grading according to diameter, is almost universally done by screens; and these devices are by far the most important ones in the whole field of grading. If the components of a fragmental or granular mass are isometric, such as are cubes, spheres, octahedrons, etc., the characteristic of a perfect or theoretical grading resulting from treatment in a battery of screens is the presence of individual particles whose axial* measure is but little less than the width of apertures of the two screens which take part in the grading. If the aperture be square, the axial measures of the limiting grains will be a trifle less than the linear dimensions of the sides of the two squares. If the aperture be oblong, the limiting criterion will be the width of the oblong openings. If the holes in the screens be round, the largest and smallest grains in the perfect grading with isometric solids will have an axial measure but little less than 0.707 d where d is the diameter of the two sizes of aperture involved in producing the grading. Where the grains are round the limits will be but little less than d .

If the grains be of tetragonal shape, that is, prisms, ellipsoids, etc., with two axes of the same length but the third longer, the criterion of the limits of the grains appearing in a particular grading will be the short axes in the case of square and round holes, or all three of the axes if the apertures in the screen be slotted. Further descriptions of the limits of grading for regular figures might be stated, but these will suffice, for with very little extension of thought they will cover all regular figures.

If a grading be of fragmental material such as would result from crushed rock, then it is evident that if one axis is selected in a particle of such a grading, any other pair at right angles to one another and the first will, within certain limits, vary as to length, the length depending upon the point they intersect the first axis. Also as the first axis is rotated in various planes its length will change within certain limits as well as the two axes at right angles to it. What then is the criterion for the upper and lower limits of grading with material of this kind? It is impossible to state it in concise language; but quite evidently, fixing the mind on one axis as the direction axis in which a fragment is passing through an aperture of the screen controlling the upper limit of a grading, then all the other pairs at right angles to it and for any point of intersection with the first must define all planes which will be bounded by the aperture figure. Otherwise, as is evi-

*The axes are taken in the same position as minereological axes.

dent, the grain will be unable to pass through. The axes, of course, do not correspond with the extreme lengths of the planes which can be drawn through them. The extreme upper limit will be a fragment having only one direction axis through which the fragment can pass through the aperture. Evidently somewhere along such axis there is a plane at right angles to it which almost makes contact at three or more points with the sides of the aperture. By a similar course of reasoning the lower limit of a grading of fragmental material can be defined. These definitions are silent as to the shape of the grain. It must be plain on a little reflection that the limiting grains might be roughly cubical or longish prisms or be disks. It is possible to conceive a longish disk of no sensible thickness which would just pass through an aperture in a diagonal position. Later on it will be clear that while such grains may be conceived to report in the undersize of a certain screen they actually, in practical operation, report in coarser sizes.

Shape of Fragments

The eye is the best guide in most cases of commercial screening. Where the grains are more or less isometric the eye will detect variations from the limits of the grading very quickly unless the particles be very small. If the grading contains scaly and longish pieces the eye may be deceived, pronouncing the grading imperfect when it may be just the opposite. With many grading problems in crushed material which tends to fracture in a variety of shapes, good commercial results are often more desirable than theoretical perfection. In the grading of abrasives, for example, what is desired in a grading is cubical or rounded grains of the same general depth of cutting edge, or grains of the same average dimension or roughly of the same volume. On this account, consequently, longish and flatish grains will be more effective if they report with cubical and roundish grains whose diameter is greater than some dimension of the first kind of grains.

Crushed material like rock or ore yields fragments which are more nearly tetrahedral (see Fig. 8) than of other shapes. The tetrahedral shape is more particularly noticeable where the rock or ore is devoid of cleavage or fracture planes. With irregularly shaped fragments there will, of course, be re-entering angles and many minor sides, but the four planes of the tetrahedron will be found to more satisfactorily bound an irregularly shaped fragment than will a greater number. It is common to assume that rock fragments are more or less cubical but it is rare to find on them six major planes which correspond to the boundaries of a cube. Some writers have considered it convenient to consider all the grains of a grading as cubes having an edge equal to the average of the width of the two screen apertures which control the limits of the grading.

Products of Coarse and Fine Crushing

In the crushing of rocks and ores the useful energy absorbed is proportional to the area of surface made in the crushing. If the surface be calculated as resulting from cubical fragments there will be error, since the individual particles depart widely from this form. In making comparisons between the work of two machines in the point of power consumption, grading analyses followed by computations of the character

which have been mentioned will show which machine is consuming the greater proportion of useful energy. It would be expected however that the shape of the fragments would change as the pieces are successively reduced in size. In coarse-crushing operations, cleavage or other pre-existing planes will largely determine the faces in the fragments of broken rock or ore. As the rock or ore becomes more and more finely reduced, pre-existing planes will more and more disappear and the particles will more and more approach ones with perfect isotropism. On this account if comparative tests are to be made with two machines they should be done with the same kind of material.

There is also some variation in the mode in which various crushing machines do their work. Where the machine applies pressure directly to the rock fragments they give way by shearing along planes inclined to the direction of application of pressure. The coarse-crushing machines break in this way, but fine-crushing machines break also by grinding actions to some extent, and the production of surface by grinding takes less power than by shearing. Grinding actions tend to round the grains, and since in the perfectly rounded grain the surface is to the surface of the cubical grain in the ratio of 3.1416 to 6, the cubical rule will report too much useful power absorption. In the fine-crushing machines there are large masses to be moved, either to do the crushing or else power must be employed to move the ore or rock from the point where it enters the machine to the point where it leaves. In some tests made by Phillip Argall at the Independence mill the friction load required for driving a Chilean mill empty was 9 hp.; with a light feed the power increased to 28 hp.; with heavy feeding, to 63; and at the limit of loading the power required was 70. Of course, the bulk of the power used is employed in raising the mullers, and the height to which they are raised increases with the load; but at the same time, as must be evident, considerable increases in power result from moving the greater masses of ore in the mill as the load increases. In coarse or medium-crushing machines the power not usefully employed is almost entirely due to the friction caused by the thrusts of crushing. This is almost exactly the case with rolls running under favorable conditions; for they are perfectly balanced machines.

A much greater source of error in assuming that the average diameter of a grading is the average of the width of the two apertures will be discussed a little later. For theoretical discussions there is no reason why the irregularly shaped particles cannot be assumed by isometric figures of equal volume, and in some discussion which follows the grains are conceived to be spheres, this shape offering the least obstacle to concise statement.

Effect of Overloading Screens

In grading with screening machines and hand screens with material less than $\frac{1}{4}$ in. in diameter, the lower limit of a grading will appear of very much smaller size than fixed by the smaller of the two apertures. In commercial grading where capacity is desired rather than precision of work, the lower limit of a grading is very much below the size fixed by the aperture. This will be evident by reference to Fig. 9, which shows an extreme case of overloading with a revolving screen and with consequent poor definition of the lower limit of the screening. The sample analyzed by a screening test, and with results as plotted on the figure, is supposed to represent material which has passed through a screen with round holes 18 mm. in diameter and has failed to pass a screen with round apertures 12 mm. in diameter. Only the cross-hatched area pictures grains which

FIG. 8 — TETRAHEDRAL SHAPE

properly belong to the grading, the excess of finer material being due to the inferior work of the screening machine and overloading. In testing the sample with hand screens the individual pieces which remained on the 12-mm. and 8-mm. test screen could readily be picked up by the fingers and tried in different axial positions to see if they were not really particles of undersize. The test work with these two hand screens is consequently 100 per cent or perfect. The sample represents extremely poor work, there being 70 per cent of the material which does not belong in the grading.

In the majority of the rock-crushing plants of the East and the ore-crushing plants of the West, the screening work will average to an efficiency of 60 per cent, there being 40 per cent in different gradings which do not belong with them. In the most precise commercial grading, the best work being done in the abrasive industry, the efficiency of the work does not actually run much over 75 per cent. As shown by hand screens the work is better than this, in some cases over 90 per cent. In making the statement about the efficiency not

FIG. 9—SIZING TEST ON MATERIAL PASSING SCREEN WITH 18 MM. ROUND HOLES

exceeding 75 per cent I have in mind a very precise mode of measurement, the unaided eye not being deemed a sufficiently accurate guide and hand screens with the finer sizes but little better.

Efficiency of Screening

If the work of a battery of screens be x per cent or any percentage less than 100 or perfect, and some particular grading, such as a $+20-12$ -mm. size, be closely probed with screens with apertures differing from one another by 1 mm., there being test screens with 19, 18, 17, 16, 15, 14, 13, 12, 11, 10 mm., etc., holes, what would be the result? There has been no experimental work to tell; but in advance of the theory it can be predicted that the plot for the number of grains resting on each size would be a hyperbola until that screen size was reached. The number of grains would then begin to decline and the curve would take a downward direction from the node and would be a hyperbola with convexity facing that of the first leg of the curve. See Fig. 10, in which diameter of grain is plotted along the axis of X , ranging from 0 diameter at the origin to 20 mm. Axis of Y is plotted for the number of grains resting on the different test screens and of uniform number for sizes above 20 mm. A little reflection will make plain that if the plot is of the form mentioned, any grading of less than 100 per cent perfection will show the greater number of grains in a grading averaging nearer the lower limit of size as defined by the smaller of the two apertures entering into a grading than the upper.

The manner in which the fragmental material has

been prepared for the grading will to some extent modify the relations shown by the curves, and they are only strictly true when there would be present in the mass fed to the 20-mm. screen the same number of fragments or grains of every size. It is, of course, impossible for the mind to conceive of more than one individual in a grading of fragmentary material of any exact volume. Again the orderly mind will be certain that there will be many sizes lacking. But let it be conceived that all the individuals of a grading can be grouped into three-dimensional isometric objects of different size, but varying from one another by regular but sensible differences in dimension and that there are equal numbers of such objects; then the plot shown in the figure will follow. The plots are based on percentages of perfect work by weight, from 60 per cent upward. As the screening work approaches 100 per cent the fewer the grains of undersize there will be in a grading and the more nearly will an arithmetical average of the width of the apertures express the average width of the grain in the grading.

Distribution of Sizes in Crushed Material

If a crushing machine be fed with fragments all of which are larger in some dimension than the discharge opening, the screen analysis of the crushed mass will show a heaping up of fragments of sizes near that of the discharge opening, and a very rapid falling off in percentage of material below such sizes. If the material fed to the crusher contains all sizes, but the bulk of it coarser than the discharge opening, then sizes below or near the discharge opening of the machine will not show such a marked falling off in percentage, although there will still be a marked heaping up of percentage in sizes near the discharge opening of the machine.

If after leaving the crushing machine the entire mass is further subjected to comminuting actions reducing it to successively finer sizes, then the heaping up which is found in the coarse-crushing gradually passes to the other end of the plot so that in very fine crushing the bulk of the weight is represented by very fine fragments. See Fig. 11.

The point to be observed for the present is that for any particular grading resulting from the screening of crushed material there may be lacking grains of a certain range of size, and in exploring any particular grading with test screens varying from one another by only slight differences of width of aperture, there might be a heaping up on some of the test screens and reverse conditions on others. It must be plain in any case that

FIG. 10—PLOT OF GRAINS

the arithmetical average of the width of the two apertures does not represent the average size of a grading.

Probability and Chance in Screening

For power-driven screens the question of the degree of freedom with which grains of various size pass through the apertures is one that can best be understood from the mathematics of probability and chance. In the ensuing theory it is assumed that the fragments or grains approach the openings in a layer 1 grain deep and that there is no interference by other grains with a grain approaching an aperture. To put the problem in the simplest form let it be assumed, Fig. 12, that there is a square-meshed opening of length of side l , the thickness of wire or stock between holes being nil. Approaching the border of the square from any direction, and with a rate of speed some elements of which will be indicated later, is a spherical grain of diameter l/n , n being assumed to be of any value equal to or greater than 1. Then evidently for the grain to fall entirely within the square it must pursue some path marked by its center projected, such that at some point in its path the center projected will fall inside the concentric square of side $l - l/n$. A little reflection will show that the chances of the grain falling through the square are in the ratio of the area of the inner square to the area between the inner square and the outer, or

$$P = \frac{l^2 - \frac{l^2}{n^2}}{l^2} = \frac{n^2 - 1}{n^2}$$

which reduces to $\frac{n^2}{2n-1} - 1$. The inverse ratio fixes the chance of the grain *not* passing through, and is also a measure of the number of squares a grain will have to pass over before falling through.

It will readily be noted that this statement of theory places the problem in its simplest form. It would be expected that if the grain were placed in any position

such that its center of gravity were within the square it would fall through the square. All such questions which by extension include impact on the sides of the aperture, the effect of which will depend on many factors, such as the angle of impact, size of particle, velocity of its motion, etc., are not considered, and, as already stated, the question of the interference of the grains with one another is not considered. The question of their interference with one another when screening *en masse* will be touched upon. The mere change of direction by impact does not modify the theory but helps it.

If the square be made with side 1 in., and n be made 8, 4, 2 and 1, the following tabulation can be made of the chance of falling through the square of 1-in. side, and the probable number of squares which grains of $\frac{1}{8}$, $\frac{1}{4}$, $\frac{1}{2}$ and 1 in. will have to cross before falling through the 1-in. square.

Size of Grain	Chance of Falling in Square, Side 1 In.	Probable Squares	
		1 in. Side to Cross, Proportional to	
$\frac{1}{8}$ in.	3.27	0.31	
$\frac{1}{4}$ in.	1.29	0.78	
$\frac{1}{2}$ in.	0.83	3.00	
1 in.	0.00	Infinity	

The number of squares to cross is taken under the simplest possible assumption, viz., that the probability of a grain falling through begins *de novo* at each opening and the grains do not follow any regular path.

If values of l , l/n be plotted as y and x as the chance, then the hyperbolas which are obtained are symmetrical, the radius of curvature increasing as the value of l increases. The average value of P , or the chance, will represent for any screen having opening side l the average chance of grains passing through from sizes l to 0. Evidently P is the area bounded by the curve between the limits y -equals-infinity and x -equals- l , and the axes of Y and X , and this area divided by l . There can be no quadrature of this area, but an approximate expression can be obtained by considering the curves as equilateral hyperbolas, taking the measure for l in a unit sufficiently small so as to substantially produce a curve of this type, and then considering the curves as tangent to the axes at distances l and to equal the quarter arc of a circle of this diameter. When the average chance is determined from figures of this kind very evidently it increases as l increases. It is in direct proportion to l . A more exact mode of solution would be to take l/n sufficiently small for the first term plotted, so that while the position of x would be at a comparatively great distance from the origin it would be a finite distance. If this be done the value of P can be determined by the methods of the integral calculus, giving as before a value for P which increases as l increases.

FIG. 12—SQUARE MESHED OPENING

greater extent, and this amounts to the same thing as the first statement. Further screening devices of the same pattern and size will have decreasing efficiency or capacity when provided with successively finer screens.

Influence of Other Factors

The question of the velocity of approach towards the screen opening will be considered for the case where the grain approaches the square at right angles to a side and along a line passing through the center of the side. The equation of a fall parabola with origin at the edge

of the opening is $x^2 = \frac{2V^2y}{g}$, where V is velocity of

approach of grain in feet per second and g the acceleration of gravity. The maximum permissible velocity with the position of path assumed is obtained when $x = l - l/n$ and $y = l/n$. Substituting these values, V becomes equal to

$$(l - l/2n) \sqrt{\frac{ng}{2l}}$$

When n equals 1 the conditions are obtained when the chance of the grain going through the aperture becomes 0, and V becomes equal to

$$(l - l/2) \sqrt{\frac{g}{2l}}$$

The shortest straight line path will be one which will bring the grain tangent to two sides of the square at some point in the travel, and the longest when the grain pursues a diagonal of the square.

It has already been pointed out to what degree test work with hand screens will permit of tests 100 per cent efficient, or perfect. With fine screens the degree

of elimination of undersize will depend upon the time spent shaking the individual test screen; but even after prolonged action of this kind there will remain many grains of very nearly the size of the openings. With machine screening the problem is different, for the fragments have only a limited amount of time for treatment, and during this time they must either pass into the undersize or discharge from the screen as oversize. Other things being equal, the screening device which yields the fewest number of undersize grains in the oversizes will be the best. In the curve Fig. 10 I have followed the theory under the assumption that the two screens, the 20 and 12 mm. sizes, will show an efficiency of 60 per cent. Under the theory the 12-mm. screen should show a different efficiency, but the tonnage reaching it is less and these two factors offset one another. No attempt has been made to measure the effects of these two opposing factors.

In Fig. 13 a curve is shown of the number of spheres below 20-mm. size required to make one sphere of 20-mm. size. From these data the weight curves on Fig. 10 have been computed and plotted.

Interpreting the Chance Law

Some further explanation may clear up some difficulties which may arise in the reader's mind. It has been stated that one ratio of the areas which have been mentioned represents the chance of the grain going through an aperture, while the inverse ratio represents the chance of its failing to go through an aperture. It has been stated further that this ratio is also a measure of the number of apertures which the grain has to cross before being eliminated if it is an undersize grain. Now on the plot for the 20-mm. screen the lower limit of undersize grains which will pass into the oversize has been fixed at 12 mm. If there be barely enough apertures passed over to eliminate all the 12-mm. grains, then all grains larger than this should report in the oversize of the 20-mm. screen, for the larger grains have not had enough apertures to pass over. I believe the reader will overcome this difficulty if he considers that while the inverse ratio is a measure of the number of squares to cross, it is the probable number of squares to cross for one grain.

The proper conception of the plot will be obtained from the following considerations. Let it be assumed that any particular size represents the lower limit for the oversize, and that there are A grains of each size, including the lower limiting size and the ones larger. Let x be the area of the chance inner square for any particular sized grain, and y the area between the inner and bounding square of the aperture. Then of A grains approaching a line of apertures of the lower limit of size, the fraction $x/x + y$ will pass through the screen and the fraction $y/x + y$ will remain in the oversize. These will be the fractions removed and remaining respectively after passing the first line of holes. Of the grains remaining there will be eliminated at the second line of holes a similar fractional part $x/x + y$, and so on, until after a sufficient number of lines of holes have been passed, all the lower limit of size has been removed. For the same number of lines of holes the proportion of undersize grains of larger sizes can then be determined, and on this being done a curve will be obtained similar to those of the oversize portions of Fig. 10. The undersize curves can be obtained by difference. I believe this explanation will also cover the difficulty in interpreting the chance law from the curves. As the law has been stated at an earlier point, there should always be fragments of all sizes in the oversizes and the plot of an oversize should pass through the origin; but the chance law is only for one aperture, and

FIG. 13—SPHERE DIAGRAM

in actual screening the grains pass over many apertures, each removing its burden of grains which do not belong in the oversize; consequently the chance law for actual screening operations must be taken in the manner explained above.

The limit of the undersize grain which does not belong with an oversize grading may be raised to any desired amount. For the 20-mm. screen, the lower limit instead of being placed at 12 mm. can be placed at a higher point between this one and 20 mm. Curves where the limit is at 15 and 18 mm. are shown. For the 12-mm. screen the limit instead of being at 4 mm. can be placed anywhere between 4 and 12 mm. Curves are indicated for 7 and 10 mm. limits. The position of the curves depends upon the number of apertures passed over. Theoretically only when an infinite number of squares have been passed over can the work of the screens be perfect, when the curves of oversizes would be straight lines. If all the grains are not treated alike, that is, do not have the same opportunities for passing over apertures, then the plot will not follow. This discordance will arise when a screen is heavily overloaded. In this case exceedingly fine grains often do not have a chance to come into contact with the screening surface at all and pass into the oversize without having undergone any screening action. Note the minus 200-mesh grains of Fig. 11, illustrated on a Tyler cumulative diagram of a screen analysis.

Unit Capacity for Flat Screens

In order to determine the capacity of flat screens for varying sized feeds, uniform conditions must be imagined. If the adjustments of a screen to which material averaging $\frac{1}{2}$ in. diameter is fed are (1) length of stroke 1 in., or somewhere proportional to the diameter of the largest material fed, and (2) number of strokes 200 per minute; then if $1/50$ -in. material be fed it is quite evident that to give the grains equal possibilities as to chance the stroke must be reduced to $1/50$ in. If this be done, the only way the capacity of the screen can be made equal to the first case would be to increase the number of strokes 50^2 times 200—an impossible number and contrary to the opening statement of this section. If the length of stroke be reduced to $1/50$ in. while the number is maintained at 200, then evidently the capacity is only $(1/50)^2$, or, in other words, the capacity is proportional to the diameter squared. If the length of stroke be maintained at 1 in. and the number of strokes be as before, 200, then evidently the capacity of the screen is proportional to the diameter. The efficiency of the screen will, however, be markedly inferior to that where it is being fed coarse material. If the diminishing average chance be considered, which falls off from size to size directly as the diameter is reduced, then evidently when all factors are equal the capacity of a screening machine varies as the cube of the diameter of particle fed. Commercial figures of capacity lie between those proportional to d and d^3 . With regard to the fine sizes it is to be observed that the eye will not detect much error in the oversizes, and a hand screen is not much superior in this respect. In the abrasive industries all that the trade demands is that the grains of a grading appear of about the same size.

Ordinary shaking screens have an advancing speed not to exceed 50 ft. per minute. The number of strokes does not exceed 300; consequently to attain an advancing speed of 50 ft. per minute the stroke has to be 2 in. or better. In actual practice it is nearer to 25 ft. per minute.

Capacity of Belt Screens

The Callow belt screen has belt speeds ranging from 34 to 100 ft. per minute. The capacity for a duplex

screen made of two endless screen-cloth belts, each having a width of 2 ft., is given by the makers as follows:

Mesh	Opening, In.	Capacity, Tons 24 Hrs.
20	.027	250
30	.0145	200
40	.011	150
60	.00916	125
80	.00675	100
100	.0055	75
150	.0041	50

These figures apparently have been determined by taking the capacity of the screen belt at the maximum speed, the grains being considered to be one deep. It follows roughly the rule for diameter. In determining the capacity of flat shaking screens, I believe 10 tons per day of twenty-four hours per square foot of screen surface, for a product ranging in size from 1 in. to 0, represents the average load. For the most precise work this figure can be regarded as the base figure also, and the square root rule followed. Under the direct ratio rule a 12-mesh screen with 0.054-in. opening would have a capacity per square foot of $0.027/0.5$ times 10, or 0.54 ton per square foot of surface per twenty-four hours. Under the square rule the capacity would be $(0.027)/(0.5)^2$ times 10, equals 0.029 tons per square foot of surface per twenty-four hours. For a 4-ft. by 5-ft. screen the capacity with inch material would be 200 tons per twenty-four hours; for 12-mesh material, by the direct rule, the capacity would be 10.4 tons, and by the square rule, 0.6 tons per twenty-four hours. These rules are only intended to apply to problems where there are successive screening operations from coarse to fine. If the problem be the use of a single screen of fine mesh to remove fine particles from a mass containing all sizes from coarse to fine, the average diameter of the particles fed will govern the capacity.

Some factors affecting capacity I do not deem worth while touching upon. Friction would be greater with the fine screens, if the apertures of a screen be considered pipes for the transport of material, for even if the stock of which the screen is composed is reduced in thickness to a degree proportional to the width of the aperture, since the number of apertures per unit of surface increases as the reciprocal of the square of the opening, the opposition to discharge must increase as the linear number of meshes increases. As a matter of fact the ratio of the weight of stock in the screen per unit of area to the area of opening increases as the number of apertures per linear unit increases, and consequently the increase of friction as the size of the apertures is diminished is something more than can be expressed by a simple ratio.

With most fragmental material produced by crushing there is an excess of the finer sizes, so with screening machinery uniform as to stroke, shape, etc., what may be proper in the way of a screen at the head of a single line of screens will show overloading for finer sizes under the rules given. But such discrepancies will have to be disregarded in practical designing, the capacity being fixed for the screen with largest apertures and the rest doing the best they can. In this connection it will be stated again that while with coarse sizes the eye will detect variations in the diameter of a very small percentage among the different pieces of an oversize, with the fine sizes it will be ignorant of variations amounting to 100 per cent or even greater. In testing with hand screens the individual screens are shaken until the eye is satisfied; and the eye being the final criterion of commercial screening, much greater capacity is satisfactorily obtained than would be permissible if exact criteria of the efficiency were used.

If a screen of any particular size receives a feed which covers it one grain deep, then if the width be diminished by a half the screen must be covered with a layer

two grains deep. If now the screen be made twice the original length then evidently the second arrangement of surface is as efficient as the first, other things being equal, unless the proportion of oversize in the feed to the screen is very great. Where the proportion of oversize of a feed is large, a broad short screen is called for. For usual screening problems a ratio of length to width of 2 : 1 is preferable. The principal objection to wide flat screens is the difficulty of distributing the feed over them. If proper distributing means are adopted there is much loss of head room. One of the principal advantages of horizontal or nearly horizontal revolving screens is that they require no distributing devices, the material to be fed being merely dumped or fed in at any convenient point. Capacities of revolving and other types of screens will be discussed later.

Denver, Col.

Lutes and Cements

A paper read at the Baltimore meeting of the American Institute of Chemical Engineers.

BY S. S. SADTLER

I use the words *lutes* and *cements* together for two reasons. First, because they have different meanings, the former referring to temporary applications and the latter to more permanent uses. Second, the use of these words conjointly shows to a casual reader that the subject of this paper is not solely with reference to Portland cement.

Quite a few years ago I read several papers on the present subject. In these papers I classified the formulæ according to composition in one instance and according to intended use in another. These papers were noticed by a number of people who communicated with me, particularly engineers.

It is very difficult to give proper credit for what one finds in the literature, as some of these formulæ are like humorous stories that are rarely traceable to a source. In looking up this subject for the present occasion I noticed some eight or ten attractive formulæ in a well-known handbook of industrial chemistry. These were credited to a periodical which I soon found quoted one of my papers, and I was not the originator of more than a few of them. Thus, things are passed on. The value of the formulæ was diminished, however, by reason of the space allotted and the changes made.

I will classify the formulæ now as I did before the Engineers' Club of Philadelphia, by the use of the following subdivisions. Very few of the formulæ given herewith have not been tried by me. The only instances are where the authority was excellent and adequate trial was not practicable for some reason.

1. Waterproof

Of the chief bituminous substances available we have pitches, asphalts, gilsonite and blown petroleum residues, mixtures of these substances and mixtures of the same with inert material.

(a) Of the asphalts I prefer a substance like refined Bermudez, as it is nearly pure bitumen and forms homogeneous solutions with suitable solvents. A minor percentage of boiled linseed oil or blown petroleum oil is useful sometimes for tempering or fluxing. For solvents heavy naphtha is generally used. It does not dissolve all the asphalt, such as the so-called asphaltene portion, but it thins out the asphalt well enough. Coal-tar naphtha is better but more costly. As voids are very apt to form in a painted asphalt coating, some form of filler is generally employed, either by coating paper so that it becomes more or less impregnated or by the addition of a filler, such as silex, infusorial

earth, etc. The natural mineral filler of Trinidad asphalt may serve the purpose of such filler.

(b) For a soft, water-tight coating in cement work, blown asphalt and infusorial earth, thinned with a solvent, such as heavy naphtha, is employed.

(c) The use of blown asphalts with natural asphalts and gilsonite is in some cases desirable, as these products are ideal fluxes for hard asphalts and tend to prevent brittleness or separation of the films when the solvent evaporates. The harder or higher melting point grades of these blown residuums are capable of making good cements alone or with filler, but are rather hard to dissolve. Such artificial asphalts have melting points as high as 150 deg. C., while the softer ones that are probably best for fluxing have melting points about 80 deg. C.

(d) Lutes of boiled linseed oil, thickened with clay, asbestos, red or white lead, etc., are waterproof, if thick enough from the filler added.

(e) Flaxseed meal made into a stiff paste with water is useful as a lute for steam connections and is easily applied.

Portland cement only serves as a waterproof cement when given time for the preliminary setting to take place. It is not generally impervious to water, and because of its colloidal character while setting it seems hard to realize that it could ever act other than as a water pervious diaphragm. But when fully or reasonably well set and dry the colloid character no longer exists and does not return to these particles that have taken part in the setting from hydration.

For all practical purposes the use of trade preparations, such as those containing metallic soaps or oil emulsions, serves to render concrete approximately impervious, but I will refer to a few points I have noticed in making or using lutes and cements.

(f) For making small experimental electrolytic cells, etc., for demonstration purposes, I have found it desirable to use white iron-free Portland cement and white plasterers' sand that had been sieved. If a one-to-two mixture is made with the prescribed quantity of an approved waterproofing substance, such as the product of the Newberry patent, and care is taken to work out voids and the article in the green is kept moist, a very nice waterproof container can be made. It will also stand dilute acids or alkalis, but not the two alternately. For large articles wire-mesh reinforcement is often desirable, and if the vessel is used for dilute acids this might well be made of a mesh of Monel metal, etc.

(g) In the literature on this subject, if it can be dignified by that appellation, one finds frequent reference to making lutes with Portland cement and silicate of soda. Some of these may work and others will not, and I approach them with caution. A little silicate of soda in the water will help toward a quick initial set, for instance, for under-water work. Water containing 4 to 20 per cent of silicate of soda by volume causes a preliminary set in 2 hr. that prevents washing away by water. It injuriously affects the natural and gradual hydration, however, unless the sodium hydroxide, carbonate or sulphate is washed out by excess of water, which is difficult to do. Mixtures containing above 4 per cent of silicate show strong efflorescence, which is particularly marked with that made with 20 per cent aqueous solution of silicate. The silicate-of-soda-setting is at first due purely to double decomposition of sodium silicate and calcium hydroxide. If very strong silicate is used the mass stiffens so fast that it cannot be worked. This is true of all concentrations of 50 per cent or over.

There is one point that might be noted. For immediate immersion in running water silicate of soda acts

as a binder, while the particles of the cement form gelatinous colloids instead of being washed away. The soluble sodium salts are more or less eliminated and apparently normal concrete results. I have used glue solutions (3 to 5 per cent strength) with white Portland cement to secure very dense compositions. It is possible that the glue aids colloid formation, and protects the same against too rapid crystallization.

2. Oil Proof

(a) Several of the best known lutes I am placing under this category, although they might be classified elsewhere:

Good glue	2 parts by weight
Glycerine	1 " " "
Water	7 " " "

The glue is first softened by the water, then liquified by heat and the glycerine incorporated. This is a good lute to render corks vacuum tight, for stopping small leaks of almost anything except water and steam.

(b) The following has been found useful in laboratories and in the works for oil vapors:

Putty of molasses and flour.

(c) The next lute to be mentioned is one of the best known and most useful. The proportions given are those I have found satisfactory:

Glycerine	90 parts by volume
Water	10 " " "

To be made into a stiff putty with

Litharge	90 parts by weight
Red lead	10 " " "

It takes several hours to stiffen and about a day to set.

(d) Several cements of which silicate of soda is an active principle or the chief binding substance are as follows:

Silicate of soda (about 30 deg. Be.)

Whiting

Made into a stiff putty.

This slowly sets by drying if not by chemical action. If magnesium carbonate be used the setting is so quick that it is hard to use the mixture. If it is used, however, the silicate should be diluted to one-third to one-half normal strength. I do not recommend either of them.

(e) Barium sulphate is often used with silicate of soda. The silicate should be about 30 deg. Be. If the mixture is heated by a preliminary heating of the silicate or it is put in a hot place there seems to be some chemical reaction which aids in the setting.

(f) A very strong and ultimately hard cement or substance for a variety of purposes is made by incorporating glue with plaster of Paris. This will be described with other plaster plastics in Section 6.

3. Acid Proof

(a) The asphaltic preparations referred to in Section 1 are largely acid proof. Black putty, the formula for which was first noticed by me in a "Handbook of Chemical Engineering," by George E. Davis, is made by intimately mixing equal weights of China clay, linseed oil and gas-tar. The ingredients must be anhydrous, so it would probably be best to take a tar residuum or very soft pitch of thick, so-called, creosote oil. Rubber cements may have varied composition, but I will only refer to two which are, perhaps, extremes. If equal parts of fresh unvulcanized rubber are used the mass is so stiff that it would be probably used alone. If as much as four parts of linseed are used considerable filler can be incorporated and make a workable putty.

(b) Equal weights of rubber and boiled oil are taken; the rubber is first dissolved in carbon disulphide in the proportion of 4 c.c. carbon disulphide to

1 gr. of cut-up rubber. Boiled linseed oil is then mixed in, and the mixing is facilitated if the oil is warm. The solvent is generally not removed by evaporation until the paste is applied.

(c) The other formula, to which reference has just been made, differs in having four times as much boiled linseed oil and then fire clay or other filler, such as siliceous, is used.

Crude, finely cut rubber. 1 part by weight

Linseed oil, boiled..... 4 " " "

Fire-clay 6 " " "

(d) Melted sulphur with fillers of stone powder cement, sand, etc., are used. The following is used for hydrochloric acid vapors:

Rosin 1 part by weight

Sulphur 1 " " "

Fire-clay 2 " " "

Linseed oil (boiled) and fire-clay stand most acid vapors.

(e) According to Davis red lead and litharge in boiled oil stand acid vapors (even nitric acid).

Litharge 80 lbs.

Red lead 8 "

Flock asbestos 10 "

Fed into a mixer, a little at a time, with 6 qt. of boiled linseed oil.

There are numerous acid-resisting mixtures possible in which silicate of soda is used. This is possible, in spite of the strong basic character of silicate of soda, because the silicate is superficially changed to colloidal silica, which continues the cementing work, at first effected by the silicate of soda.

(f) Barium sulphate, powdered glass, China clay, etc., are used with silicate of soda slightly diluted with water. A strength of about 30 deg. Be. is close to what is best for the purpose.

(g) The following I have used with success for dilute hydrochloric acid:

White China clay 1 part by volume

Fine white sand, or powdered

quartz and sand 2 " " "

are mixed thoroughly and worked up with just enough silicate of soda, diluted with an equal volume of water to make a paste. This can be rendered more impervious to water by the judicious incorporation of organic colloids. If a little fine casein be incorporated with the silicate of soda in a mixer so that the mixture is quite smooth the mass will be better. About 5 per cent of fine, dry casein powder is added, based on the weight of silicate. If fresh milk curd can be used, corresponding to the same dry weight of casein and allowance is made for the water contained, a mechanical mixer may not be needed.

4. Chlorine Resistant

(a) The most reliable are made with Portland cement as chief ingredient:

Powdered glass 1 part

Portland cement 1 "

Silicate of soda..... 1 "

The last mentioned should be diluted considerably so as not to set too fast.

Portland cement quickly reacts with silicate of soda, but powdered glass and clay react more slowly with silicate of soda, but finally render the cement insoluble as regards its mass.

5. General Purposes with Plaster of Paris

This series of lutes and cements is highly important, and individual formulae will serve to prevent the escape of hydrocarbon and other gases in furnace work, as cements for mechanical purposes and as coatings, such

as plaster, when mixed with asbestos straw, plush trimmings, hair, etc.

(a) Soluble sulphates form double sulphates with calcium sulphate and with water. They set harder and are more impervious than calcium sulphate (plaster of Paris) alone. It is desirable not to take equal molecular quantities to form the full double sulphates, but about half of these quantities. Sodium, potassium and aluminum sulphates are used for this purpose.

(b) According to Sigmund Lehner, a little borax in the water used makes hard cements and regulates the setting: 12 volumes water to 1 volume saturated borax solution sets in 15-20 min. at 10 deg. C.; 8 volumes water to 1 volume saturated borax solution sets in 1 hr. The same author gives a formula credited to Viotti for a weatherproof plaster cement.

(c) One thousand five hundred grams of borax and 150 grams of magnesium oxide are melted together and powdered. This powder is then mixed with 75 grams of plaster of Paris. Borate of magnesium thus predominates and protects the plaster from being washed away by water.

6. Marine Glue

Standard preparation of this class of lutes, (which are applied to crevices, etc., hot, and get firm but not brittle when cold) is composed as follows:

Crude rubber	1 part by weight
Shellac	2 " " "
Pitch	3 " " "

The rubber is first dissolved in carbon disulphide or turpentine before mixing with the heated (not superheated) mixture of the other two. The advent of blown petroleum residuums has made it possible to make up hard but flexible compounds without rubber. Grahamite is a good base to which fluxes, such as these just mentioned or soft asphalts, are added.

7. Gasket Compositions

There are so many good gasket compositions on the market that I was on the point of omitting all reference to them. For factory work I have found no trouble in getting ropes of graphitized asbestos, rubber composition leather fibers cemented with rubber, etc., that are quite satisfactory.

In the laboratory one can generally make out for low temperatures and pressures by saturating heavy "kraft" wrapping paper with soft pitch, such as wood pitch for steam or with gelatine and glue (hectograph) composition for oils. For high pressures, slots filled with lead rings and a V-shaped rim to the lid are most satisfactory.

8. Machinists' Cements

A few words might be said here with reference to machinists' cement. These are the well-known red and white leads. The red lead is often diluted with an equal bulk of silica or other inert substance so as to make it less powdery on drying. The best way that I have found to accomplish this, however, is to add rubber or gutta-percha to the oil as follows:

Linseed oil	6 parts by weight
Rubber or gutta-percha..	1 " " "

The rubber or gutta-percha is dissolved in sufficient carbon disulphide to give it the consistency of molasses, mixed with the oil, and left exposed to the air for about 24 hr. The red lead is then mixed to a putty. Oxide of iron makes less brittle cements than red lead.

9. Leather Cements

As cements of this class are apt to be wanted by chemists sometimes, I quote from my paper in the *Transactions of the Engineers' Club of Philadelphia*, XXI, 4, 1904.

The following formulæ are given in the "Papier Zeitung," Vol. 18, p. 2618:

"(a) Equal parts of good hide-glue and American isinglass, softened in water for 10 hr. and then boiled with pure tannin until the whole mass is sticky. The surface of the joint should be roughened and the cement applied hot.

"(b) One kilo of finely shredded gutta-percha digested over a water-bath with 10 kilos of benzol, until dissolved, and 12 kilos of linseed oil varnish stirred in.

"(c) Seven and one-half kilos of finely shredded india-rubber are completely dissolved in 10 kilos of carbon disulphide by treating while hot, 1 kilo of shellac and 1 kilo of turpentine are added, and the hot solution heated until the two latter ingredients are also dissolved." Precautions against fire and vapors should be observed.

(d) Another one noticed in the "Journal of the Society of Chemical Industry":

Gutta-percha	8 ozs.
Pitch	1 "
Shellac	1 "
Olive oil	1 "

These are melted together.

10. Iron Cements

When iron in a fine state of division, as in fresh oil-free filings or cast-iron borings that have been powdered, is mixed with an oxidizing agent, such as manganese dioxide or a substance electro-negative to iron, such as sulphur, in a good conducting solution like salt or salammoniac, galvanic action sets in very rapidly, ammonia is given off (if salammoniac be used) and the iron swells, by forming iron oxide, and cements the mass together. It is best diluted with Portland cement. A formula which I give from memory is:

Iron filings	40 parts
Manganese dioxide, or flowers of sulphur	10 "
Salammoniac	1 "
Portland cement	20 to 40 "

Water to form a paste.

These cements are used extensively in foundries, etc.

I prefer manganese dioxide to sulphur as a negative element. The free carbon of cast iron that has been powdered is negative pole enough to react, but the use of manganese dioxide causes quicker action. If not diluted with cement they are apt to expand too much and bulge out from the hole or crevice in the iron.

11. Crucible Cements

(a) Mixtures of clay and borax in which the clay predominates. Silicate of soda and powdered glass or sand are the best known compounds for cementing lids on crucibles, etc. Sometimes the "iron cements" are used for such purposes, or iron filings and a little manganese dioxide are added to the above compositions for crucible cements.

(b) Probably the best known cement for graphite is fire-clay, which with water binds the graphite fairly well and itself stands high temperatures.

(c) In some cases it is desirable to have an all-carbon binder, and for this purpose tars or soft pitches are used. Very little binder must be used, however, or the material will crack when heated, as the carbonizing of the pitch shrinks the binder somewhat. Starch paste has been recommended for this purpose, but the shrinkage is greater and the binding is not as good.

(d) A strong, waterproof cement that will stand high temperatures may be made by mixing powdered silica or fine sand and powdered silica with a solution of magnesium chloride of about 10 per cent strength. This composition is applied as a putty and then painted

or soaked in a solution of silicate of soda of about 30 per cent strength. This forms magnesium silicate as a binding material for the silica.

13. Magnesia Composition for Furnaces, Etc.

Magnesia burned at incandescent heat or hard-burned, 80 per cent. Magnesia light burned (just sufficient to drive off carbon dioxide (dull redness), 20 per cent. The composition is made into a stiff putty with water and shaped as desired. The water must be driven off very slowly. A small proportion of good asbestos fiber may be worked in to keep from cracking.

14. Oxy-Chloride Cements

These are sometimes called stone cements and the only one of practical importance is that made with magnesium chloride.

If the magnesium chloride is quite pure, i. e. free from potassium or calcium chloride, the solution used need not be more than 18 deg. Be., but if commercial German magnesium chloride be used it requires a solution of 20 to 22 deg. Be. The magnesium oxide must be freshly burned at a dull red heat as the light oxide that is requisite for this cement readily absorbs carbon dioxide from the air and becomes unsatisfactory or of no use for making cement compositions. A diluent for the magnesium oxide is generally used, such as silica or wood pulp, ground wood, etc.

This communication is not offered as being an exhaustive treatment of the subject, but as an attempt at bringing together only tried or traceable formula for the making and using of lutes and cements.

Science and Aesthetics

From Dr. JOHN A. BRASHEAR's presidential address before the American Society of Mechanical Engineers (Dec. 7, 1915) we cull the following paragraphs:

"Dr. Maclaurin tells us a story of Matthew Arnold, the apostle of sweetness and light, in which he is made to say that when a candle burns the oxygen of the air combines with the carbon in the candle to form carbonic gas, *but who cares?* The story is told because it suggests an attitude to science that is far from rare, even among people of intelligence to-day. He recalls the poetic query of Keats when he writes of the rainbow: 'Do not all charms fly at the mere touch of philosophy? There was an awful rainbow once in heaven, we know her woof and texture. She is given in the dull catalog of common things. The complaint seems to be that science with its analysis of color robs us of the pleasing sense of awe and mystery, but if you dig deep you will find enough mystery left to satisfy the keenest yearner after half lights and the obscure. At best, science replaces one mystery only by another of grander order.'

"Now, leaning for a moment from the purely utilitarian side of science to the aesthetic, there comes a joy to the lover of the beautiful that cannot be expressed in words, for he sees in the color of an American Beauty rose the same light waves that tint yonder red star, whose light waves, coming to him at the rate of 180,000 miles per second, left it a thousand years ago. He listens to the varying bell tone of the swiftly moving locomotive and translate it into the motion of stellar worlds, whose distances have never before been measured by the most refined modern instruments.

"Does the photographic picture of your favorite landscape lose any of its beauty when you are told that during an exposure in your camera of only one-tenth of a second from forty to eighty millions of millions of light waves have hammered upon your negative tending to

shatter them to pieces or change their molecular arrangement?

"Maclaurin gives a charming illustration to help us better understand what it means when a ray of violet light impinges on our photographic plate for one-tenth of a second. 'Imagine you are watching a log floating near the seashore, and that it strikes against a pier as it rises and falls with the waves, say, once in six seconds. In order to correspond to the number of light waves in one-tenth of a second, the log would have to beat up against the pier for more than two million years.'

"But enough for the present of the aesthetic side of science, though it has beauties in its every phase, whether it be in the flower or in the rainbow—whether it be in the structure of glass from which the prism is made, or the story it tells of yonder far-off universe. But can we connect this science beautiful with our engineering problems? Why not?"

Analysis and Assay of Zinc Retort-Residue

The smelting of Western zinc ores leaves a retort residue which is sometimes valuable for its content of gold, silver, lead or copper, or some combination of these metals. It is customary to resmelt these residues in lead blast furnaces. In some cases the residues are handled by the company originally selling the zinc ore, and in others by the zinc-smelting company itself. In either event, the practice has brought new problems to the analytical chemist in determining the valuable constituents, on account of the large quantity of carbon left in the residue and the refractory character of the sintered material. In the early history of residue analysis, chemists found difficulty in obtaining concordant results and in checking each other, due largely to the fact that the methods applicable to ores were not wholly suited to retort residue, as well as to a lack of uniformity in the methods adopted. These difficulties have now been largely overcome, and we present some of the methods adopted at various places. Constructive criticism is invited in the hope of making the methods more exact and efficient.

Details of Analysis

The following methods are in use at the Hillsboro, Ill., plant of the American Zinc Company of Illinois:

Carbon.—Weigh 1 g. of the residue into a casserole, add 15 c.c. HCl and boil five minutes. Add 30 c.c. hot water, clean the casserole thoroughly and filter through a weighed filter, washing with hot water. Remove the filter and contents and dry at 100 deg. C. Weigh and ignite until all carbon is burned. Weigh the ash, and calculate carbon as the difference between the weight of the ash plus filter paper and the weight of dry carbon plus filter.

Zinc.—To the filtrate from the carbon determination, add 15 c.c. ammonia and 1 c.c. hydrogen peroxide, and boil until all peroxide is expelled. Filter and wash with hot water. Dissolve the precipitate in the original beaker with a little HCl and reprecipitate as before, filtering through the same filter. To the filtrate add 20 c.c. HCl, and if copper is present remove it by adding 10 g. test lead and boiling for ten minutes. Determine the zinc volumetrically by titration with standard solution of potassium ferrocyanide, using ammonium molybdate as indicator.

Iron.—Dissolve the precipitate, obtained by the above treatment, in the original beaker with dilute HCl (1:3). Wash and boil. When boiling hot add, drop by drop, a saturated solution of stannous chloride until the solution is clear. Cool and add 25 c.c. saturated

solution of mercuric chloride. Determine iron volumetrically by titration with a standard solution of potassium bichromate, using a weak solution of freshly prepared potassium ferrocyanide as indicator.

Sulphur.—Weigh 1 g. of the residue into a 50 c.c. crucible and mix thoroughly with 10 g. Eschka's mixture (two parts MgO , one part Na_2CO_3). Heat slowly over a Bunsen burner until all carbon is expelled, stirring frequently with a platinum rod. Dissolve the mixture in dilute HCl , add 1 c.c. hydrogen peroxide, boil and filter, washing the residue thoroughly. Precipitate sulphur as barium sulphate by the addition of barium chloride, and boil for five minutes. Allow to settle and then filter, wash, ignite and weigh as barium sulphate. The weight multiplied by 0.1375 gives the equivalent of sulphur.

Lead.—Weigh 2 g. of the residue into a 200 c.c. flask and add 10 c.c. HNO_3 , 6 c.c. HCl and 10 c.c. H_2SO_4 . Boil to white fumes, cool, dilute with 50 c.c. water, boil, filter and wash. Dissolve the lead sulphate thus obtained in a clean beaker with hot ammonium acetate, and after washing thoroughly add 20 c.c. of a 10 per cent solution of potassium bichromate. Allow to settle and then filter, washing thoroughly. Place the filter and lead chromate in a clean beaker, add 50 c.c. water and exactly 1 g. ferrous ammonium sulphate. Add 50 c.c. HCl and titrate the excess iron with standard solution of potassium bichromate. Lead equals 1.226 times the difference between total iron in 1 g. ferrous ammonium sulphate and the amount found by titration.

Copper.—To the filtrate from the above add an aluminium cylinder large enough so that one-third of its surface will not be immersed in the solution. Boil until all copper is precipitated; remove the cylinder, rinse thoroughly and dissolve the adhering copper into a clean beaker. If any copper remains behind, filter and add to that dissolved from the cylinder. Dilute the solution, add a slight excess of ammonia and titrate with standard solution of potassium cyanide.

Determination of True Silica

The exact determination of silica (SiO_2 , not insoluble) requires unusual precautions under ordinary circumstances, but seems to offer particular difficulty in retort residue. The method used at Hillsboro is as follows:

To 1 g. of the residue add 20 c.c. aqua regia and run to dryness. Bake in order to dehydrate soluble silica. Cool, add 15 c.c. HCl and boil five minutes. Dilute with 30 c.c. hot water, filter and wash. Place the filter and contents in a platinum crucible and burn off the carbon. Mix the ash with 10 g. Na_2CO_3 and fuse. When the fusion is quiet, cool and remove to an evaporating dish, preferably platinum, and dissolve the melt with water and HCl . Evaporate to dryness and bake until no odor of HCl can be detected. Add hot water and HCl and filter through an ashless filter, washing until the filtrate shows no chlorine. Ignite and weigh as SiO_2 .

At the Ohio & Colorado smelter, where retort residue is smelted, the procedure for silica is slightly different. One-half gram of the sample is mixed with 6 g. of sodium peroxide in a 20 c.c. nickel crucible, and covered with 2 g. sodium hydroxide (a stick about $\frac{3}{4}$ in. long). Fuse in an assay muffle at a faint red heat. The action once started is violent and soon complete. Allow the crucible to stand for three minutes at a temperature slightly above the melting point of the mixture, finally removing it to a casserole to cool. Cover with a watch glass, and cautiously fill the crucible with cold water. When the action ceases, fill the crucible again, after which the melt should be completely dissolved. Remove and carefully wash the crucible. Now add HCl until the solution clears. If black particles

are visible in a residue, the decomposition has been incomplete and the assay must be repeated. Evaporate to dryness, but avoid baking so hot that a black color appears. If the residue is a light brown, the operation has been properly conducted. Cool, moisten with 20-25 c.c. conc. HCl , add 100 c.c. water and boil. Filter through an ashless filter and wash free from chlorides. Dry, ignite and weigh as SiO_2 , doubling the weight to obtain percentage.

In one of the Denver custom laboratories the method is still more exact, special precaution being taken to prevent the loss of soluble silica. The weighed sample is treated with aqua regia and evaporated to dryness. A second similar treatment is given, and as the evaporation nears completion, a little HCl is added. When finally dehydrated, the residue is treated with dilute HCl , boiled and filtered. The filtrate is retained for further treatment. The insoluble thus obtained is fused in a platinum crucible with a mixture of sodium and potassium carbonate, cooled, dissolved in dilute HCl and twice evaporated to dryness. The residue, which is SiO_2 , is treated with hot water and HCl , boiled and filtered, combining the filtrate with that first obtained. The combined filtrate is now evaporated to dryness, taken up in dilute HCl and filtered. Additional SiO_2 , to the extent of from 1 to 2 per cent is thus obtained, and is added to the larger quantity, ignited and weighed.

Assay for Silver

At the Ohio & Colorado smelter the nitre-crucible assay is used, taking $\frac{1}{2}$ A. T. of the residue in a 20 g. crucible. The fluxing mixture is 20 g. soda, 4 g. silica, 35 g. litharge, and an amount of nitre determined from the following procedure: Determine the carbon in 1 g. of the residue by igniting in an assay muffle and weighing the ash, and from this figure determine the carbon in $\frac{1}{2}$ A. T. Compute the amount of nitre necessary to oxidize this amount of carbon to CO , and for purposes of the assay use this calculated amount of nitre less 2 g. It amounts usually to from 9 to 12 g. The fluxing mixture and residue are thoroughly mixed, covered with 10 g. soda and a teaspoonful of borax glass. Fuse slowly at a low heat for about half an hour, as the assay will boil over if the initial heat is too high. After the charge has settled quietly in the crucible, raise the heat as high as possible and pour. The resulting button is cupelled in the usual manner.

A very satisfactory method is one used at some zinc smelters and by certain custom assayers. The flux contains nitre in amount sufficient, as determined by experience, to give the right size lead button when $\frac{1}{4}$ A. T. of the residue is used. As the amount of carbon varies in the residue, it may be necessary to make an occasional preliminary assay and vary the amount of nitre according to the result obtained. Little or no trouble is experienced from boiling, and the method is reported to give entire satisfaction.

Purification of Water by Ozone.—To correct a misprint in our issue of Feb. 1, page 160, it should be stated that the cost of purification as carried out by the Baltimore County Water & Electric Company at the present time is less than \$2.00 per 1,000,000 gal. of water treated. Besides the aluminium electrodes and micanite dielectric tubes a feature of particular interest in the system is the aspirator tubes used for drawing the ozone through the generators and mixing the gas with the water. The system was developed by the chief engineer of the company, Mr. A. E. Walden. Mr. S. T. Powell presented an interesting paper on this system at the recent Baltimore meeting of the American Institute of Chemical Engineers.

The Use of Low-Grade Phosphates*

BY JAMES A. BARR

When phosphate mining operations first commenced in Tennessee the loss of both high- and low-grade material was large, because of the crude hand methods employed. Practically all rock smaller than 2 in. was thrown back into the pits and covered up with the overburden of subsequent openings.

With the advent of mechanical washers and other mining machinery, together with the abolishing of the contract system, the waste has been steadily diminished, until at present only the finest sand is being rejected; and even this is not lost, for in the majority of cases the water, slime and sand from the washers are run into large settling ponds where practically all of the phosphate-bearing material is caught and stored for future use, or until it is profitable to ship lower grades.

The latest equipment used to recover the fine and lower grades of phosphate sand includes Dorr thickeners, settling tanks, Dorr classifiers and settling ponds served by locomotive cranes with clam-shell buckets, making it possible to save material averaging as fine as 200 mesh. To attempt saving finer material would necessitate a different type of drier, which might be patterned after the multiple-deck roasters.

The present tailing runs from 15 to 25 per cent of available phosphate, which, however, as mentioned before, does not represent a total loss to possible future operations. The demand of the consumer is the greatest factor in regulating the recovery at present.

In the mining of blue rock, which does not require washing treatment, the main waste material is the capping of low-grade kidney formation, generally used for backfilling of the rooms.

By reason of the introduction of improved methods in the early stages and the re-mining of territory skimmed over at the start, at the present time the net result of all operations is a comparatively small loss.

One of the largest temporary losses in the industry occurs in the Florida pebble district, where the recovery of phosphate runs about 25 per cent. The loss is classed as temporary because most of the tailing has been collected in ponds and piles, where it may be reclaimed in the future should developments or improved processes warrant.

In cleaning the Florida pebble phosphate, aside from the elutriation of the clayey binder and strata that sometimes contaminate the rock, the main operation is that of sizing, by which the large phosphate grains are separated from the smaller silica sand. This results in the loss of all the fine phosphate along with the silica. Owing to the similarity of the two in specific gravity, no mechanical process has been developed as yet to effect a further saving.

PROBLEMS AWAITING SOLUTION

As the problem now stands, the development of some concentration process is required to effect a further recovery of the low-grade phosphate in Tennessee and Florida, where the consumers demand a high-grade product.

Taking 68 per cent tricalcium phosphate as the present minimum average grade for Florida pebble and Tennessee blue rock, and 72 per cent for the Tennessee brown rock, it will be seen that the development of such a concentration process is a much needed step in the conservation of the phosphate resources, for by its introduction the commercial limits for use in complete fertilizers could be reduced to 60 per cent and possibly 50 per cent tricalcium phosphate.

In the event of low grades of phosphate becoming commercial products, 20,000,000 tons would become available within a 50-mile radius of Mount Pleasant, Tenn., alone, and perhaps 100,000,000 tons of rock, especially if phosphatic limestone is taken into account. These figures are not claimed to be precise, but are given to indicate that the available phosphatic resources have, so to speak, merely been scratched.

It would seem that the most feasible means for making low-grade phosphate commercially available lies in the development of a smelting or electrometallurgical process whereby the phosphorus content of the rock would be rendered available (soluble) directly and without the introduction of a diluent, as in the manufacture of acid phosphate by the sulphuric acid method. By such a direct conversion, a 60-per cent rock would serve the same purpose as a 72 to 75-per cent rock with the sulphuric acid method.

Along these same lines a combination process may be developed whereby low-grade phosphate and an insoluble potash feldspar or similar potash mineral may, by heat or other treatment, be rendered available for use as a commercial fertilizer. The European war has brought out the importance of such a discovery.

Again, there might be developed another combination process whereby ammonia phosphate could be made directly, as cyanamid is now manufactured with the aid of an electric furnace.

DIRECT USE OF PHOSPHATE ROCK AS FERTILIZER

The greatest possibility of using low-grade phosphate lies in the direct application of finely ground rock to the soil in the raw state, allowing the acids of nature to convert it into soluble forms. One authority on farm fertilizers has said that in the majority of cases a mixture of raw ground phosphate with stable manure makes one of the best fertilizers.

The difficulty with the ground phosphate trade has been that the fineness of grinding was not such that a sufficient percentage of the commercial product became available within any reasonable time. When the grinding industry was new, the fineness was generally 90 per cent through 80 mesh, while now it is 90 per cent through 100 mesh, or even finer. The impalpable powder gives effective and immediate results; therefore the future extension of this particular phase of the phosphate industry will be aided greatly by finer grinding.

Another available source of phosphorus is basic slag from steel manufacture. The United States Steel Corporation has erected a plant in Alabama to prepare such slag for fertilizing purposes and has placed the product on the market.

This form of fertilizer has been successfully used in Germany.

An average grain crop requires and takes about 15 lb. of phosphorus per acre from the soil in which it is grown. This phosphorus must eventually be replenished, for with a meager amount of phosphorus in the soil the crops are poor, and with none the harvest is nil. The majority of farmers fail to replenish the soil with the elements taken out by the crops, and at no very distant time they will be drawing heavily on our phosphate resources.

In view of this, the use of the lower grades is certain to become common.

International Agricultural Corporation, Mount Pleasant, Tenn.

Lead and Zinc Smelter to Reopen.—The lead and zinc smelter in Webb City, Mo., will be reopened shortly and will be operated by the Picher Lead Co. of Joplin. This smelter has been idle for several years and when in operation will employ about 100 men.

*A paper to be presented at the New York meeting (February 14 to 17) of the American Institute of Mining Engineers.

The Hydrometallurgical Treatment of Complex Gold and Silver Ores

A Paper Presented at the Second Pan-American Congress, Washington, D. C., December 27, 1915, to January 8, 1916.

BY G. H. CLEVENGER

The term "complex ore" has never been clearly defined, nor is it probable that it ever will be. If defined upon the basis of the ability to obtain a high extraction, an ore which could be treated at a profit and a high extraction realized could be called a *simple ore*, no matter how complicated the process for realizing this end might be.

Then, again, the classification might be based upon the nature of the process necessary for the satisfactory treatment of the ore; thus an ore which required a complex process or combination of processes might be classified as a *complex ore*, while an ore with which a simple process sufficed might be called a *simple ore*. The latter suggestion seems to be the more logical basis for a classification. But it would be difficult if not quite impossible to draw the line as to where a process ceased to be simple and where it became complex, as this would be largely a matter of personal opinion upon which there could be no general agreement.

Despite the difficulty of satisfactorily defining a "complex ore" there is a constant effort being made to treat ores by hydrometallurgical methods which have previously resisted such attempts, and metallurgists are also constantly endeavoring to develop more simple and direct processes of treatment which will either result in a higher extraction, lower working costs, or both.

Historical

The present status of the hydrometallurgy of gold and silver is perhaps best understood by going back to the beginning of hydrometallurgical practice and briefly tracing the various developments down to the present day.

The oldest hydrometallurgical process, if such it really could be considered, was the simple operation of panning in water a gold-bearing sand or ore which had been crushed between stones. This was soon supplemented by the passage of the finely ground ore with water over the hair side of the skins of wild animals.

The next development was the *early Roman amalgamation process*, first described in Pliny,¹ which was conducted by agitating the pulverized ore with mercury and water in earthen vessels. Since this process was only effective for the recovery of metallic gold or silver from simple ores it was but natural that the *early European amalgamation process*,² capable of treating more complex ores, particularly those of silver, should be developed. The prominent features of this process as ordinarily carried on was the grinding of the ore in a stone mill with water, mercury, salt, and some compound of copper. At times other reagents were added, but they were not essential. Although this process was in use in various parts of Europe at a much earlier date, it was first described by Biringuccio³ in 1540.

Bartolme Medina introduced the *Patio*,⁴ or, as it was sometimes known, "*Mexican Amalgamation Process*," at Pachuca, Mexico, in 1557. The finely ground ore, moistened with water, was mixed with mercury,

copper sulphate and salt on large stone-paved areas (patios) by the treading of horses or mules. Since all the mercury at this time came from Europe, it seems probable that Medina had as a basis for the development of this process a general knowledge of the European process of amalgamation.

Be this as it may, great credit was due him for this new and novel metallurgical process which made possible for the first time the treatment of large lots of ore by a hydrometallurgical process at a reasonable working cost. So thoroughly did he adapt the general principles of amalgamation to the special conditions met with in Mexico that few improvements were ever made in the original process, which held the field for the treatment of silver-gold ores in Mexico until within recent years, when the cyanide process, capable of giving a higher extraction of the gold and silver, was developed to the point where it could be more economically applied than the Patio process.

The *Cazo* or *Fondo process* was invented by the priest Barba,⁵ residing in Bolivia, while experimenting as an alchemist in 1609. This process comprised stirring the finely ground ore with water, mercury and salt in a copper kettle heated over a fireplace. Until about 1793 the Fondo process was used in South America and Mexico with but few variations from the method as originally described by Barba. At about this time a larger vessel having a copper bottom and wooden sides, in which the stirring was done by mule power, came into use. This was known as the *Fondon process*.⁶

The *Tina process*,⁷ employing an iron-bottomed wooden vessel, in which the ore was ground in water and amalgamated with mercury, was used at Kongsberg, Norway, for treating native silver ores. A modification of the Norwegian Tina process⁸ was also used at a later date in Chile for treating simple ores.

The chloridizing roast for silver ores, introduced by Born,⁹ was first combined with the Cazo process¹¹ at Schemitz, Hungary, in 1786. Barrel amalgamation¹² in combination with the chloridizing roast was first introduced at Hålsühütte, near Freiberg, in 1790.

The *Washoe process*,¹³ developed through the combination of the California stamp mill with an elaboration of the Norwegian Tina for fine grinding and amalgamation (pan) and the chemicals of the Patio process, was introduced for the treatment of Comstock ores in 1860. This amalgamation process, adapted to American conditions, rapidly assumed the same position in the United States for the treatment of silver-gold ores as was occupied by the Patio process in Mexico for the treatment of the same class of ores.

A later development when treating complex ores was to give a chloridizing roast preceding grinding and amalgamation in the pans. This was known as the *Reese River process*.¹⁴

The *Kröhnke*¹⁵ process of barrel amalgamation was introduced into Chile in 1862, but had a limited use. The date of the first use of amalgamated copper plates

as now used for the treatment of simple gold ores is not definitely known, but it seems probable that it began by supplying the inside of the mortar with copper plates, suggested, no doubt, by the use of the copper kettle in the Fondo process; this was followed by the use of plates outside of the mortar. Outside plates were in use as early as 1856¹⁶ at Grass Valley, California. Previous to this the metallic gold was collected upon the hairy side of the skins of animals, blankets or other rough surfaces.

The *Batopilas*¹⁷ process of amalgamation in pans with cyanide solution was described in 1911. The *Nipissing*¹⁸ process of amalgamation in a siliceous-lined tube mill with very strong cyanide solution was introduced early in 1911. The processes so far considered were all amalgamation processes. In 1848 the *Plattner chlorination process*,¹⁹ the earliest lixiviation process, was introduced. In this process an oxidizing roast of the ore preceded its treatment with chlorine gas. Through the suggestions and work of a number of men, the more modern process of *barrel chlorination*²⁰ was evolved in 1890. This process was more suitable for the treatment of large tonnages of ore than the Plattner process. *Vat chlorination*²¹ was the latest development in gold processes employing chlorine as a solvent.

A silver lixiviation process based upon the chloridizing roast of the ore followed by leaching with a solution of sodium hyposulphite was introduced in 1858 by von Patera.²² This was followed in 1860 by the proposal of Kiss²³ to use the calcium salt rather than the sodium salt on account of the supposed greater solubility of gold in calcium hyposulphite. In 1884, Russell²⁴ introduced the use of an extra solution of sodium-copper hyposulphite and sodium carbonate for precipitating the lead.

The *Augustin*²⁵ and the *Zierogel*²⁶ processes, introduced in the 40's, were used in a limited way almost exclusively for the treatment of matte. However, the recent application of the Augustin process²⁷ in connection with blast roasting for the treatment of low-grade complex silver ores containing lead and copper is worthy of note.

The first proposal for the treatment of gold and silver ores by cyanide solutions was made in 1867 by Ray,²⁸ although *Elkington*²⁹ had found in 1840 that gold was soluble in cyanide solutions with the aid of electricity, and *Bagration*³⁰ had discovered in 1842 that gold was soluble in cyanide solutions without the use of electricity. *MacArthur and Forrest*, in 1886,³¹ developed a process employing dilute solutions of cyanide, and zinc

precipitation. About the same time *Siemens*³² developed a process employing very dilute cyanide solutions and electrolytic precipitation.

It has required almost thirty years and the work of many men to bring the cyanide process to its present high state of perfection. Originally the cyanide process was only considered generally applicable to the treatment of simple gold ores and on account of the lack of suitable means for treating the slime high extractions were the exception rather than the rule, so that the cyanide process did not at once become a serious competitor of the older processes. The Plattner chlorination process for limited amounts of high-grade gold concentrate and the barrel chlorination process for large tonnages of siliceous gold ores continued to hold the field for the treatment of complex gold ores, and plate amalgamation with or without concentration for simple gold ores. The Patio amalgamation process in Mexico, and the Washoe amalgamation process, and to a less extent the hyposulphite lixiviation processes in the United States, continued to hold the field for treating silver-gold ores.

Cyanidation was first used to supplement the recovery made from gold ores by plate amalgamation. With the introduction of fine grinding and the various types of slime filters, it became a formidable rival of the older processes of amalgamation and chlorination for the extraction of both gold and silver. As the operation of the process became better understood, it gradually displaced the Patio process in Mexico, and the Washoe and chlorination processes in the United States. To-day all of the older processes of amalgamation, with the exception of plate amalgamation and the Nipissing process, are obsolete. The same may be said of chlorination, which made its last stand in treating the Cripple Creek telluride ores. The hyposulphite silver leaching processes long since became obsolete without ever becoming an important factor in ore treatment.

The cyanide process, with the exception of plate amalgamation and the Nipissing process, therefore, at the present time entirely holds the field for the hydrometallurgical treatment of gold and silver ores. For the purpose of discussion in this paper, amalgamation is considered an accessory operation. The advantage of treating both gold and silver ores by the same process is apparent. Silver was not recovered in the chlorination process and, if present to an appreciable extent, interfered with the gold extraction through the formation of insoluble silver chloride. Attempts to recover the silver by a subsequent treatment with sodium hyposulphite solution did not prove satisfactory. The silver amalgamation and lixiviation processes did not recover a high percentage of the gold and left much to be desired in the recovery of the silver. Unfortunately, gold and silver do not occur in ores in the sharply defined lines drawn at times by the limitations imposed by certain processes of ore treatment. The cyanide process being both a gold and a silver process, has the necessary flexibility regarding the recovery of the two metals from the same ore.

Preliminary or Accessory Operations

In order to properly consider the preliminary or accessory processes or operations which are available for use in conjunction with the cyanide process for increasing its effectiveness, it will be necessary to return to certain of the earlier processes and consider the function of certain of these operations as carried on in them.

The *oxidizing roast* was first applied as a preliminary operation with the old Plattner chlorination process for

¹⁶ The writer has corresponded with R. W. Raymond, the late S. B. Christy, and many others familiar with early metallurgical development in the United States, in a vain endeavor to ascertain where and by whom amalgamated copper plates were first used in the recovery of gold. Mr. W. L. Oliver has informed me that amalgamated copper plates were in use as early as 1856 at Grass Valley, California, U. S. A.

gold. Roasting was absolutely essential to the successful operation of all the chlorination processes. The oxidizing roast should never be used in conjunction with any process for the recovery of silver, on account of the fact that it renders a large proportion of the silver refractory to all known hydrometallurgical processes, including the cyanide process.

The reactions occurring during roasting and the final chemical combination, or physical change of the silver existing in an ore at the end of the operation, have never been determined. This is a matter which is well worth careful investigation, as it appears that we have the same phenomenon to deal with in the treatment of certain naturally occurring oxidized ores of silver, particularly those containing oxidized manganese minerals. My own researches have led me to believe that the silver is not in combination with manganese, but that probably the oxides of manganese have exerted an influence upon the occurrence of the silver through their behavior as oxidizing agents. Certain silver ores containing the oxides of manganese are not refractory to cyanide treatment, but this fact in no way controverts the above theory.

The oxidizing roast as practised with the chlorination process is still employed in conjunction with the cyanidation of certain of the higher-grade sulphide and sulpho-telluride gold ores. It is significant that but little of the small proportion of silver which these ores generally contain is recovered during cyanidation. Several hundred tests made under the writer's direction have indicated that the raw sulpho-telluride ores (containing approximately 1.0 oz. of gold per ton) of the Cripple Creek district, with certain exceptions, will yield almost as high an extraction when ground very fine and given a long period of agitation as when treated by the common practice of roasting, followed by regrinding and cyanidation. The raw ore under the above conditions also yields a quite good extraction of the silver which is invariably below 1.0 oz. per ton. Notwithstanding this fact, the roasting process so far as we now know, under the conditions of cheap fuel and a roasting cost of 50 to 60 cents per ton, still holds the field for the following reasons: It is not necessary to grind so fine; the extraction is a matter of hours rather than days; the cyanide consumption is less and the solutions are less likely to become foul. However, investigation is constantly going forward in this direction, and it would not be surprising if raw treatment would eventually win out.

A recent development in the roasting of ores preliminary to hydro-metallurgical treatment is the application of blast roasting or continuous suction roasting machines of the Dwight-Lloyd type. This bids fair in certain cases to meet all the requirements of roasting and to reduce the cost of the operation materially.

The thoroughness of the roast determined whether the results were good or bad in the chlorination process and, while this is less true in the cyanide process, yet proper roasting is of prime importance if the best results are to be realized. It seems probable that careful investigation of the whole problem of roasting would eliminate the irregularities which sometimes arise. The oxidizing roast is only applicable to gold ores, and then only when the results are sufficiently improved, as regards extraction or costs, to justify its use.

The chloridizing roast, introducing salt during the roast, was first applied in connection with the Fondon process, and later became quite generally used with the barrel amalgamation process, the Washoe process and the silver lixiviation processes for treating refractory ores. The chloridizing roast has never been favored for gold ores on account of the high volatilization losses;

in fact, this is also its weakest point with silver, since silver chloride is quite volatile. It has been used at times in conjunction with the cyanide process, but its use in this connection has entirely passed out. It is claimed that volatilization of the silver is entirely under control in the newly-proposed system of blast and suction roasting. One possible application of the chloridizing roast under favorable conditions is in connection with the treatment of the so-called refractory manganese-silver ores, as most of the silver is converted into readily soluble silver chloride.

The losses of gold and silver occurring during roasting in a well-regulated plant have never been accurately determined, and, indeed, it would be a most difficult thing to do. Although such losses may be small, they constitute a factor which cannot be ignored.

Water concentration was applied in conjunction with many of the earlier processes, as, for example, the Patio and Washoe processes. It was early introduced, following simple plate amalgamation, for the purpose of augmenting the recovery from gold ores. Eventually all the tailing from the modern barrel chlorination plants were concentrated before being discarded. Concentration is a valuable adjunct of the cyanide process and has been practised both when crushing in water and when crushing in solution.

Generally the operation precedes cyanide treatment, on account of being more conveniently applied at this point, but in many cases it would be advantageous if it were feasible to have it follow cyanide treatment. When it precedes cyanide treatment, a considerable proportion of the readily soluble gold and silver may be removed in the concentrate, when it might be more advantageous to recover them as bullion. In the case of low freight rates and favorable smelter contracts this may be an advantage rather than otherwise; but for the majority of plants the more gold and silver turned out as bullion the better. Therefore, the ideal practice in most cases would be to recover all the gold and silver possible as bullion by the cyanide process and then concentrate the tailing to recover as high a percentage of the remaining gold and silver which had escaped dissolution as feasible. Obviously there are many cases where the percentage of extraction of gold and silver from the residue leaves no margin for concentration.

At times concentration can be introduced into the cyanide flow sheet to advantage for the purpose of removing the minerals which are difficult, if not impossible, to treat by the regular milling scheme, so that they may receive the special treatment necessary without having to incur the expense of subjecting the whole tonnage to the special treatment made necessary by a comparatively small proportion of refractory minerals. On the other hand, the introduction of concentration adds to the first cost of the plant and the complexity of its operation, so that these disadvantages must be carefully weighed against the advantages which are likely to accrue.

Chemical reduction is one of the latest developments in preliminary treatment and was, therefore, not used in conjunction with any of the earlier processes. Such a process is most feasible when carried on in an alkaline solution, as acids attack the gangue of most ores. Reduction may be accomplished through the use of dilute caustic soda solution with aluminium or zinc, or through electrolysis in a suitable solution by bringing the ore to be reduced into intimate contact with the cathode.

The only commercial application of reduction is at the Nipissing low-grade mill, where caustic soda and aluminium are used for converting silver sulphide and sulpho-antimonide minerals into metallic silver prior to

cyanidation. This preliminary treatment lessens the period of agitation necessary with cyanide solution.

Many experiments involving the preliminary reduction of telluride gold ores in caustic soda solution with aluminium and zinc, as well as cathodic reduction in both caustic soda and salt solution, have shown that with cheap fuel and efficient roasting this form of preliminary treatment would present no advantage. The gold telluride compounds are in general more difficult to reduce than the sulphide and sulpho-antimonide silver minerals.

Amalgamation, particularly plate amalgamation, is an important preliminary treatment with gold ores which contain any considerable proportion of readily amalgamable gold. In fact, in certain cases where a considerable proportion of the gold occurs native, the bulk of the extraction may be effected by amalgamation. However, the cyanide process is necessary for recovering the portion not recovered by amalgamation.

There is considerable difference of opinion among metallurgists regarding the extent to which amalgamation should be applied in hydro-metallurgical work. Those having the extreme point of view maintain that with sufficiently fine grinding to bring all the gold or silver to the degree of subdivision necessary for rapid dissolution, amalgamation may be dispensed with and the whole of the gold recovered by cyanidation. This can be done in certain cases, even with silver ores where a considerable weight of metal is involved, but it means a higher cost for grinding and generally also a higher cost for cyanide treatment and, therefore, may not be so profitable as coarser grinding and amalgamation followed by cyanidation.

Special types of amalgamation, such as the tube mill amalgamation practised at the Nipissing mine at Cobalt, Ontario, Canada, becomes absolutely necessary in the case of the very high-grade silver ores treated in this district which contain a large proportion of native silver, or closely allied minerals.

Flotation, the most recent development in ore dressing, which has become such an important factor in the recovery of the rare metals from their ores, is becoming a valuable adjunct to the cyanide process in connection with the treatment of the precious metal ores. Recently very good experimental results have been obtained upon refractory manganese-silver ores by giving a preliminary sulphidizing treatment followed by flotation. Flotation in alkaline solutions is also a recent development which promises much.

The data now available indicate that flotation may be used prior to cyanidation for removing minerals interfering with cyanide treatment, such as the sulphide copper minerals or such minerals as the tellurides and certain silver minerals which might be more advantageously removed in this way than decomposed and dissolved by cyanide. In most cases the tailing from flotation appears to be amenable to cyanide treatment, but the concentrate is not, even though there be no refractory mineral present. Gold concentrate is amenable to cyanidation after roasting, but silver concentrate is not on account of the refractory combination of silver formed by the oxidizing roast. Metallurgists are at work upon this problem and it is quite possible that a solution will be found in the near future.

The treatment of the tailing from cyanidation is a most attractive field, particularly since flotation in alkaline solutions has become possible. So far flotation has not been accomplished in cyanide solutions. Another very attractive field is the direct treatment of very low-grade ores which would not pay to cyanide. In many such cases a high extraction could be obtained, the tailing rejected and the concentrate cyanided or

shipped. This proposal is, of course, made upon the assumption that certain of the difficulties which now stand in the way of treating flotation concentrate will be overcome.

Important Factors in the Operation of the Cyanide Process

Inasmuch as the cyanide process is of vital importance in the present-day hydrometallurgy of gold and silver, a discussion of the more important controlling factors of the process is in order.

The degree of comminution of the ore is one of the most important factors, particularly in the treatment of silver ores. The purpose of grinding is to free the gold and silver minerals from the inclosing gangue and to reduce the mineral particles to such a size that they are readily dissolved. Grinding should be carried on in such a manner as to waste as little power as possible in grinding the worthless gangue and still fulfill the above named conditions to the fullest extent possible, since the less the mineral is protected by the gangue and the greater the surface of the mineral exposed to the solution, the more rapid the rate of dissolution.

It then follows, for example, in the case of certain silver ores, that while fine grinding may not produce any greater ultimate extraction, yet in general it will materially reduce the time of treatment necessary. But this advantage is not always realized without the disadvantage of greater consumption of cyanide arising, since finer grinding not only causes a greater surface of the minerals containing the precious metals to be exposed to the solution, but also a greater surface of those minerals, if present, which may act as cyanicides. Careful correlation of the time of treatment with degree of comminution may serve to minimize this difficulty.

Selective grinding whereby the heavy mineral particles are ground finer than the lighter particles of gangue takes place automatically to a greater or less degree in closed circuits where hydraulic or mechanical classifiers are employed so that actually in the majority of plants the heavy mineral particles are ground finer than the gangue. The additional cost of finer grinding, together with the attendant disadvantages which may arise, must in each case be carefully weighed against the additional extraction possible, or the decreased time of treatment necessary to obtain a given extraction.

The concentration of the solution of cyanide is a vital point. In general, the stronger the solution, within certain fairly well defined limits, the more rapid the dissolution, and, furthermore, the less the interference of a given percentage of impurity which might be present in solution. On the other hand, a greater proportion of impurity may be dissolved by the stronger solution. In the case of a plant which is operating at forced capacity a stronger solution may be used to advantage in order that the maximum extraction may be attained under this condition of operation. Stronger solutions may result in increased cyanide consumption, although the magnitude of this loss in a properly operated plant is not so great as has been supposed.

However, in a plant where there is considerable mechanical loss of solution the additional cyanide loss would prove an important factor. For this reason a strong solution is not generally favored when continuous decantation is used. The tendency in some cyanide plants has been to use a lower concentration in cyanide than that capable of giving the highest economical result. This probably is through the fear of excessive cyanide loss.

The alkalinity both as regards the kind of alkali and its concentration is perhaps only second to the concen-

tration of the solution in cyanide in importance. The effective alkalis are the alkaline hydroxides, the most available being caustic soda and lime. Lime in contact with the solution becomes calcium hydroxide, slightly soluble, but sufficiently soluble to be effective as an alkali in cyanide treatment. Lime in the majority of localities is much cheaper than caustic soda and, fortunately, is in the majority of cases the most satisfactory alkali to use. Many of the impurities which form soluble sodium salts form with calcium insoluble compounds which are eliminated with the tailing, thereby maintaining the solution at a higher degree of efficiency. There is evidence to indicate that when certain antimonial minerals are cyanided caustic soda may prove the more satisfactory alkali; this, however, is not definitely proved, and most certainly is not true in all cases.

The concentration of alkali, or as it is usually termed the protective alkali, may vary from practically 0 to 100 points.* At the Homestake a very low alkalinity is conducive to the best extraction, while in treating raw Cripple Creek ores a rather high alkalinity, employing lime, results in the highest extraction and the lowest consumption of cyanide.

Dilution or ratio of solution to dry ore in the pulp undergoing treatment is generally recognized as a factor to which proper attention must be paid if the highest extraction is to result. If a higher dilution is used than is necessary the capacity of the plant is cut down, and, on the other hand, if the dilution be too low the maximum extraction is not attained. It is quite impossible to give general figures for minimum dilution as these figures vary for different ores. In general, lower dilutions can be used with gold ores than with silver ores, probably on account of the greater weight of metal to be dissolved in the latter case. Other conditions being equal, it appears that lower dilutions can be used with the Pachuca agitator than with the mechanical agitator on account of the greater proportion of air brought in intimate contact with the pulp.

The time of treatment depends upon the character of the silver and gold minerals and upon their degree of comminution, and, as previously pointed out, also upon the concentration or strength of the solution in cyanide. It therefore follows that finer grinding, or increase of the cyanide concentration of the solution, or both, will in general result in reducing the time of treatment necessary. In cases where the cost of power is high, and as a consequence the cost of fine grinding would be excessive, the ore may be ground to the point where the minerals are liberated from the gangue and then separated into sand and slime, the slime being treated by agitation followed by either decantation or filtration. The sand containing the coarse mineral particles requiring a long period of contact with the solution for dissolution can be given the long period of contact necessary at a reasonable cost by leaching. Cases of this kind clearly indicate where combined sand and slime treatment can be employed to advantage.

The method of precipitation employed, assuming equal efficiency as regards the precipitation and recovery from solution of the precious metals, may exert an important influence upon extraction, either through introduction of the precipitant used into solution or its failure to precipitate certain interfering elements. For example, zinc in the presence of arsenic may interfere in the treatment of certain ores. If aluminium precipitation is used the difficulty is overcome through

the elimination of zinc. When copper reaches a certain concentration in solution difficulties arise with both extraction and precipitation. Neither zinc nor aluminium precipitate copper to any extent, hence if copper is to be removed from solution electrolytic precipitation must be used.

Carbon, which at times occurs in gold and silver ores, may occasion difficulty in cyanidation. It has been generally assumed that carbon occurs in gold and silver ores in the form of graphite, but the evidence available by no means supports this view in all cases. The two extremes of carbon as regards its behavior in cyanide solutions are graphite and charcoal. Graphite is dense and does not possess pores, therefore cannot occlude gases, while charcoal is porous and has the property of occluding relatively large volumes of gases. Graphite does not precipitate gold and silver from cyanide solutions while charcoal does. Intermediate between these two extremes are various forms of carbon which will precipitate gold and silver to a greater or less extent.

Feldtmann²² has shown that the graphitic or carbonaceous schist from the mines of West Africa will precipitate gold from cyanide solutions roughly in proportion to the carbon content or the schist. Gold so precipitated is not soluble to any appreciable extent in fresh cyanide solution, but is soluble in sodium sulphide solution. He thinks that the compound formed is possibly carbonyl aurocyanide, which may react with sodium sulphide according to the below equation:

The only gold ore containing carbon which I have had an opportunity of investigating carefully showed but little tendency to cause premature precipitation. This fact, together with its general appearance, led to the conclusion that the carbon in this ore was largely graphite. However, the graphite was found to definitely interfere with cyanidation. Experiments with deflocculation of the colloidal portion of the ore including the graphite gave negative results, but it was discovered that if the physical state of the graphite were altered, most conveniently by heating, that the extraction was wonderfully improved. The results in Table I show clearly the effect of heating.

Practically all gold or silver ores can be treated by the cyanide process or by the cyanide process in combination with some other preliminary or accessory treatment, with the exception perhaps of certain ores containing a considerable amount of copper, lead, etc. In such cases, the desirability of recovering the base metals leads to smelting the ore upon either the lead or copper basis, and the necessity for hydrometallurgical treatment for the recovery of the gold and silver disappears since the precious metals are recovered by the smelting operation in connection with the base metals. Despite the fact that most ores can be successfully treated by the skillful application of the cyanide process, either alone or in combination with other accessory operations, it cannot be said that such treatment is

*The writer has long used a system of alkalinity numbers, similar to the system proposed by Sherwood, except that instead of using a $n/5$ solution of acid, an empirical solution (in the case of oxalic acid 11.6071 grams per liter) is used. When a 50 c.c. sample of solution is taken for titration, each 0.1 c.c. of the acid required corresponds to 1 point of alkalinity; 100 points correspond to a saturated solution of lime in water at ordinary temperatures.

²² Precipitating Action of Carbon in Cyanide Solutions. W. R. Feldtmann. Trans. Inst. Min. and Met., London, April, 1915.

always profitable, so that much remains to be done in the way of simplifying and lowering the operating costs of hydrometallurgical processes for the treatment of gold and silver ores, and in many cases improving the percentage of extraction.

Exemplification of Present-Day Adaptation of the Cyanide Process.—A clearer understanding of the possibilities in connection with the treatment of complex ores will perhaps be gained from a consideration of the solution of certain ore treatment problems which are exemplified by some of the adaptations of cyanidation in use at present for the treatment of a great variety of ores. On account of the high percentage of the precious metals recovered, the ores treated may not be looked upon as being complex ores. Certain of the cases which are now cited as an accomplished fact at one time could not be treated, or were treated by a single simple process and a very much lower extraction realized. The metallurgical practice at the older mines has been largely a matter of evolution. For example, the cyanide process has been added to plate amalgamation; it has displaced the chlorination process, and has been combined with concentration for the treatment of a great variety of gold and silver ores.

Example A.—The Homestake mine³⁴ (Lead, S. D., U. S. A.) produces a low-grade gold ore (\$3.59 per ton) in which a considerable proportion of the gold occurs in the metallic state, therefore recoverable by plate amalgamation. However, this ore did not yield a high extraction, according to present standards, by plate amalgamation, although the process was carried to the extreme limit of its possibility through the introduction of an unusually large plate area. This was on account of the occurrence of a portion of the gold intimately associated with pyrite and arseno-pyrite. The recovery by plate amalgamation, the original process, was first supplemented by concentration, then concentration was discontinued and the cyanide process was introduced for treating the whole of the pulp. This recovered a much higher total percentage of the gold and permitted the shipment of the whole product as bullion. The pulp is separated into sand and slime—the sand treated by leaching in vats and the slime by leaching in the Merrill filter press. Table II gives the extraction results.*

TABLE II. HOMESTAKE MINE

By amalgamation upon regrinding.....	0.8
By cyanidation from sand.....	15.1
By cyanidation from slime.....	9.7
Total by amalgamation and cyanidation (in 1914).....	94.6

Example B.—The Treadwell mine³⁵ and ³⁶ (Douglas Island, Alaska) produces a lower grade gold ore (\$2.85 per ton in 1914) than the Homestake. It is possible to make a considerable recovery of the gold by plate amalgamation. A portion of the gold in this ore occurs intimately associated with pyrite, therefore concentration has from the beginning followed plate amalgamation. The early practice was to roast the concentrate

and treat it locally by the Plattner chlorination process; later it was found more economical to ship the concentrate to Pacific Coast smelters. At the present time the concentrate is reground and cyanided locally so that this company ships its whole product as bullion. Unlike the Homestake, the balance of the tailing does not pay to cyanide. Table III gives the extraction results.

Example C.—The Cripple Creek ores³⁷ (Cripple Creek, Col.), of moderate grade (+1.00 oz. gold per ton), in which very finely divided native gold and the telluride minerals of gold, and to a slight extent those of silver, occur intimately associated with pyrite and other sulphide minerals, were formerly treated by roasting and barrel chlorination followed by concentration. The present practice is to roast, regrid in cyanide solution, concentrate on woolen blankets, separate into sand and slime, cyanide the sand by leaching and treat the slime either directly by pressure filters or by agitation and vacuum filtration. The blanket concentrate is either melted directly or is treated by amalgamation.

The general principle of blanket concentration is one of the most ancient of gold recovery processes, and therefore an operation which the modern metallurgist is prone to condemn when he first sees it in operation in a modern mill. However, careful investigation increases his respect for this time-honored method of gold recovery when he finds that under the special conditions obtaining in these plants it is performing a most useful function in a most economical manner. Table IV gives the extraction results.

TABLE IV. CRIPPLE CREEK

Example D.—The Portland Gold Mining Company's low-grade Cripple Creek ores,³⁸ generally below 0.15 oz. gold per ton (Cripple Creek, Col.), are of the same general character as the higher grade ore. The ore is crushed in cyanide solution, concentrated, and the sand separated from the slime. The sand is rejected, as it is too low-grade for further treatment, but the slime is cyanided. The concentrate is shipped a short distance to the smelter. Although more profitable under present conditions to ship the concentrate, it could be roasted and cyanided locally, or might possibly be treated by very fine grinding and direct cyanidation. Table V gives extraction results.

Example E.—Goldfield Consolidated mine³⁹ and ⁴⁰ (Goldfield, Nevada) formerly produced a high-grade complex gold ore (average November, 1909, to Oct. 31, 1910, —1.785 oz. per ton), but as operations have continued

*The figures given for extraction in the different examples are not in all cases the same as those which have appeared in descriptions of the practice which have previously appeared. This comes about either through the realization of a better extraction on account of improvements in the practice or a decreased extraction through increased complexity of the ore. The brief resums of practice and figures for extraction given are strictly up to date and authoritative with but one exception. In this connection the writer is indebted to the following well known managers for supplying the necessary information and giving permission for its publication: Mr. Fred Bradley, Mr. Allan J. Clark, Mr. G. M. Taylor, Mr. Theobald H. Croese, Mr. A. H. Jones, Mr. R. B. Watson, Mr. J. W. Hutchinson, and others.

the grade has become lower. The old practice was to crush in water, amalgamate, concentrate and cyanide. The concentrate was treated by a special process and the residue shipped to the smelter. In the present practice amalgamation has been dispensed with and the concentrate is treated locally by cyanidation after roasting. Table VI summarizes the results.

Example H.—The Nipissing mine⁴³ and ⁴⁴ (Cobalt, Ont., Canada) produces a low-grade complex siliceous silver ore containing sulphide, antimonide and sulpho-antimonide minerals of silver together with many other impurities, as arsenic tellurium, cobalt, nickel, etc. The ore is crushed in a caustic soda solution followed by extremely fine grinding in the tube mill and reduction with aluminium. After filtration it is cyanided by agitation and filtration. During the early operation of the

mill the ore averaged 26.0 oz. silver per ton, but more recently it is of lower grade.

Percentage of extraction by cyanidation.....92.0 per cent

Example I.—The Nipissing mine⁴⁵ (Cobalt, Ont., Canada) also produces a very high-grade complex silver ore containing upwards of 10 per cent of silver, which occurs chiefly metallic and as dyscrasite with a variable proportion of the sulphide and sulpho-antimonide minerals of silver. The gangue is largely the arsenical minerals of cobalt and nickel containing tellurium, antimony, mercury and metallic bismuth. The ore is ground in a silex-lined tube mill with very strong cyanide solution and a large proportion of mercury. This is followed by cyanide treatment comprising agitation and filtration of the pulp.

	Per Cent
Percentage of extraction by amalgamation.....	98.0
Percentage of extraction by cyanidation.....	1.0
Total.....	99.0

1. If the ordinary uncorrected assays are used, the bullion recovery frequently approximates 100 per cent.

Example J.—The Alaska Gastineau Mining Company⁴⁶ (Juneau, Alaska) produces a very low-grade gold ore (\$1.25 per ton), having a slate, gabbro and quartz gangue in which occurs free gold, pyrite, pyrrhotite, galena and a little sphalerite. The ore is crushed and concentrated in water by ordinary gravity methods and the concentrate shipped to the smelter. Percentage of the gold extracted 84.0 per cent. This is a good exemplification of the application of the large scale methods which have been so successful in connection with the treatment of the low-grade porphyry copper ores to a gold ore which would be too low grade to be treated by any other method.

The following proposals for certain special cures of ore treatment are intended to be merely suggestive, as they are by no means fully proven nor do they entirely cover the range of possibilities. It is further realized that much investigative work is necessary to properly apply flotation in all cases to the treatment of gold and silver ores.

Proposal 1.—Very low-grade gold or silver ore which, owing to its complex nature and lowgrade, cannot be profitably treated directly by cyanidation:

Proposal 2.—Gold or silver ore containing sulphide, copper or zinc minerals which would interfere with cyanidation:

Proposal 3.—Typical gold or silver ore amenable to cyanidation where flotation might be applied to the tailing for the purpose of augmenting extraction:

Proposal 4.—Gold ore of moderate grade containing graphite which interferes with extraction:

Proposal 5.—Gold or silver ore in quartz or other gangue not acted upon by acid, containing oxidized copper minerals in sufficient amount to interfere with cyanidation:

Chemical Exhibition at Urbana Meeting of the American Chemical Society

The chemistry department of the University of Illinois is arranging an exhibition of chemical industries to be held in conjunction with the spring meeting of the American Chemical Society and the dedication of the new chemistry building at the University of Illinois, Urbana, Ill., April 17-21, 1916.

It is the purpose of the committee to emphasize especially the importance of American chemicals and apparatus, and at this critical time to make them better known. A large attendance of chemists is expected at the meeting, in addition to the 2000 students registered for courses in chemistry at the University of Illinois.

No charge is made to exhibitors for floor space; a nominal charge to cover the cost of printing a catalog will be made. Necessary gas, water, electricity and drayage will be furnished free. No admission fee is to be collected at the door.

Prof. H. L. Olin, Chemistry Building, University of Illinois, Urbana, Ill., is the chairman of the exhibits committee.

The Anaconda Copper Co. was forced to close its mines on Jan. 29, owing to the intense cold. The ore was frozen in the bins and cars and it was impossible to transport it to the smelters. After a few days' delay operations were resumed.

The Operation of the Blast Furnace The Sequences of the Charges which Occur

BY J. E. JOHNSON, JR.

The three articles on the principles of the blast furnace, published in recent issues of this journal, have necessarily to some extent formed a picture of the operation, but we may now consider in more detail the progressive changes which take place within the stack, first, in the raw materials as they descend, and second, in the gas as it ascends.

The Progress of the Raw Materials

While the changes through which these pass shade from one into another so that the number of stages is literally infinite, yet these stages may be divided into four main zones, first, that of drying and warming; second, that of the reduction of the ore, the decarbonating of the stone, and some solution of coke; third, incipient fusion, and the early stages of slag formation; fourth, the reduction of the last remaining portions of the ore from the slag, the completion of the carbonization of the iron, its siliconization, and also its impregnation with the phosphorus and manganese to the extent these may be present.

THE WARMING AND DRYING ZONE

As to the warming and drying zone not very much need be said. In coke furnaces in good practice there is a sufficient amount of residual heat in the gases at their exit from the stock column to give them a temperature of seldom less than 300 or 400 deg., and ranging from this up to a thousand, as we have seen in the article on thermal principles. This provides an ample interval between their temperature and that of the incoming raw materials to provide for the rapid drying and warming of the latter so that the temperature of the charge rises quite rapidly for a short distance below the stock line, and thereafter much more slowly because the temperature interval is much reduced by this rapid warming of the cold incoming stock.

THE ZONE OF REDUCTION

In passing through the second zone, the ore and fuel react with the ascending gases according to the complex laws set forth in the article on chemical principles. In a broad way oxygen is continually taken from the ore and imparted to the gas so that the content of oxygen in the latter constantly rises in its progress through this zone, but in detail we have the complicated reactions whereby the CO of the gas is broken by the catalytic action of the iron ore into CO₂ and C, the latter being deposited as an impalpable dust in the interstices of the charge, thus obstructing the free passage of the gas through it and not infrequently raising the resistance in this zone and the pressure below it. This carbon dust is carried down with the charge to a zone of higher temperature in which the ore can no longer remain in equilibrium with the carbon, so that the latter takes part of the remaining oxygen from the ore, is reconverted into CO, and rises again with the rest of the gas, perhaps to go through the same reaction again.

In this zone also the carbon dioxide of the limestone is driven off by heat, the greater portion of this action probably taking place in the upper portion of the zone. This, of course, results in adding to the gas additional CO₂ which entirely alters the equilibrium relation between the gas as a whole and the ore and carbon of the charge, a portion of the latter being absorbed by the gas to reduce a part of this CO₂ to CO and restore the equilibrium.

Frank C. Roberts several years ago called attention to a case in which a furnace which had been using a coarse, lumpy limestone changed to a rather finely crushed stone, with the result that slips became much more pronounced. The operators finally decided that the change in the size of the limestone was the cause of the slips and upon going back to the larger stone these were accordingly reduced to what they had been before the change was made. Mr. Roberts accounted for this on the hypothesis that with the lumpy stone, because of the time required for the heat to penetrate the large lumps, decarbonization was delayed down to the point where carbon deposition was taking place freely. The result was that the CO_2 from the stone dissolved the carbon dust deposited and prevented it from obstructing the interstices in that zone, leaving a free passage for the gas. With the smaller stone, on the other hand, the CO_2 was driven off at a level above that at which the carbon deposition took place, and the latter was, therefore, not removed by this agency, with the result that a tight zone was formed with slipping as a direct consequence.

I have no experience of the conditions described myself, but the explanation, in addition to being very ingenious, is entirely reasonable and illustrates how difficult it is to determine in advance the effect of any given change on the operation of a furnace, for it is almost universally believed and is probably very generally true that limestone crushed down to a reasonable size is very much to be preferred to coarse, lumpy stone.

Where the ores charged are in the form of lumps, or particularly if the ore be magnetite, the action of reduction is very much slower and the individual pieces of ore may descend well down toward the top of the bosh before they are disintegrated by the reducing action. If the ores are both magnetic and lumpy both causes contribute toward a still further delay in reduction, and we are likely to have solid lumps of ore descending into the bosh and even into the hearth of the furnace, where it is certain that they are reduced by the direct action of carbon with all the loss of both heat and fuel which have been shown to inhere in that action. Such furnaces must inevitably suffer from a fuel consumption materially higher than that of a furnace working on ores inherently more reducible or better prepared. On the other hand, we have come within recent years to realize that ores may cause almost as great fuel loss by being too reducible as by being too irreducible.

With the introduction of large percentages of Mesabi into the burden, the universal experience was that the furnaces worked very much more irregularly with more frequent and much more violent slipping and kicking, with not infrequent explosions of a much more violent nature which we will consider later, and that the fuel consumption was materially increased, even on furnaces working, for the time being, free from slips; so that the increased fuel could not be charged to the irregularity of the descent of the material into the hearth.

The reason for this increase in fuel does not seem to have been understood by anyone until within a year or two. In the summer of 1913 I obtained some authentic data as to the quantity of blast required to burn a pound of coke based on a vast amount of accurate and reliable investigation at one of the largest plants in the country. This amount was 51.4 cu. ft., whereas the amount required to burn a pound of the same coke, if there were no solution loss, under the same circumstances, would have been about 63

cu. ft. Obviously, then, the solution loss under these conditions was about 20 per cent.

I had recently been making some investigations based on the practice described in the paper of Mr. Arnold K. Reese before mentioned, in which the solution loss based on both engine displacements and gas analysis seemed to have been very small, while the fuel consumption for this run which was made altogether on Old-Range ores was, if not a record, at least within a few pounds of any authentic record made until very recent months. What could cause this enormous difference in the solution loss? It may be remarked that making allowance for the solution loss in modern practice the amount of fuel per pound of iron actually burned in front of the tuyeres was almost identical in the two cases, perhaps about a hundred pounds higher in the modern practice, corresponding to a slight increase in the slag volume as compared with Reese's comparatively rich mixture, the difference accounted for by solution alone amounting to about 400 lb. per ton of iron.

The difference in the physical condition of the ore was the only notable difference in the two cases. In Reese's practice the ores were Old-Range, so either lumpy or plastic, and contained no fine sandy material, whereas in the case taken from modern practice the burden was some 80 per cent Mesabi. When a layer of lumpy or plastic ore is charged upon a layer of coke it has little opportunity even after thorough drying out to run down into the interstices of the coke; the lumps, of course, cannot so run and the plastic material when dried out becomes not powdery but lumpy and is, therefore, almost equally unable to penetrate through the coke charge.

With fine, sandy ores the conditions are totally different. As soon as the ore becomes thoroughly dried a large portion of it runs almost like a liquid, especially when in a state of constant agitation caused by the gas current passing up through it, and this portion of the ore rests not only upon the top surface of the coke charge, but runs all through it and makes contact with the coke practically throughout the mass of the coke charge. It must be remembered that ferric oxide and carbon in contact at any temperature above a few hundred degrees are essentially in unstable equilibrium, and that direct action takes place between them, a part of the oxygen of the ore attacking the carbon and carrying it off as CO.

With the Old-Range ores this action could only take place along a single plane of contact, but with the fine, sandy ore scattered throughout the mass the number of points of contact is almost infinitely increased, and obviously the solution loss must necessarily be very much higher under these circumstances than with lumpy or plastic ores.

This, then, taken with the effect of solution loss set forth in the article on thermal principles, forms the explanation of the greatly increased fuel consumption of furnaces working fine ores over those using ores of similar analysis but different physical characteristics.

There has been for many decades, and probably many centuries, a strong prejudice among furnacemen against the use of fine ores, and it is probable that this action just described is responsible for a great portion of this prejudice. Moreover, with certain kinds of fine ore the conditions may be even worse. Furnaces working on fine magnetic concentrates have had the greatest difficulty in securing regular work, irrespective of the care with which the furnace might be burdened and filled, for the reason that the fine ore, as the furnacemen expressively de-

scribe it, "runs ahead." That is to say, under the agitation of the gas current it runs almost like a liquid, not only down through one fuel charge but perhaps through several if the conditions happen to be just right, and owing to its irreducibility, and to its having reached the hearth perhaps several hours ahead of the fuel which should have accompanied it, the furnace is unable to carry the additional load and serious trouble results.

In recent years much progress has been made in treating fine ores before charging them so as to convert them into some form of lumps. This was originally undertaken with the purpose of preventing the very fine portions from being carried out by the top gases and lost, but it has been found that in some cases a real benefit to the operation of the furnace has been brought about, and the reason for this improvement is believed to be that set forth above, that the physical structure of the ore is so changed as to prevent its running through the charge. Perhaps in some cases also, the lumps act as a blanket on top of the coke to prevent fine portions of the ore charge from finding their way down into the coke. Several of these processes reduce the ore partly to the condition of magnetite and thereby decrease its reducibility, but leave the product so porous that the gas and heat have free access to its interior portions, and so prevent its acting as do the large irreducible lumps of magnetite above described.

Throughout this zone of preliminary reduction a continual warming up of the ore takes place, partly by the physical absorption of the heat of the ascending gas current, and partly by the action of the oxygen of the ore in oxidizing the CO formed in the hearth to CO_2 , a reaction which gives off more heat per unit of oxygen than is absorbed by the removal of the same amount from the ore and therefore produces a net increase in the amount of heat present.

It will be noted from the equilibrium diagram in the chapter on chemical principles that the equilibrium line for both Fe_2O_3 and FeO descends toward the right or high-temperature side of the diagram, which means that as the quantity of oxygen remaining in the ore is reduced a higher heat and higher percentage of CO in the gas is required to remove the remaining portions, and as the ore descends these are precisely the conditions into which it passes, a continually increasing temperature, and increasing concentration of CO in the gas until at the top of the bosh practically all the carbon in the gas is in that condition.

It is probable that it is because of the long slow slope of these equilibrium lines that this second zone of the furnace requires to be the largest of any in point of size, almost as large as all the other three put together, so that time and space may be allowed for the relatively small but approximately constant reaction pressure (to coin a crude term), to do thoroughly and well its work of preparing the ore as completely as possible for the final operations which take place in the hearth and bosh.

Many other reactions and changes probably go on within this region but from the point of view of operation these are the only ones with which we need to concern ourselves.

THE ZONE OF PRELIMINARY SLAG FORMATION

This zone is one located approximately at the top of the bosh where, as we have previously seen, the materials pass through a pasty stage and finally into a fluid slag, but one by no means of the composition which subsequently is tapped from the furnace.

In a paper of Mr. F. E. Bachman before the American

Iron and Steel Institute in October, 1914, occurs the following paragraph which describes in a few words better than anything I have ever seen the action which I believe takes place in this zone.

"My conception of the formation of a blast furnace slag is that at a point approximately 25 feet above the tuyeres the minerals which have the lowest melting point in the ore begin to melt, then the free SiO_2 combines with FeO and with the melted minerals forms a fusible slag somewhat similar to heating furnace cinder. This slag flows down over the pieces of lime and coke, and when it reaches the hotter section of the furnace, the FeO is gradually reduced to Fe and replaced by CaO or by CaO and MgO from the lumps of burned stone. In front of and immediately above the tuyeres the coke ash is set free and combined with the slag produced above, and a portion of the lime not completely fluxed often passes below the tuyeres and is absorbed in the bath of slag in the hearth."

It may be doubted whether in practice other than that described by Mr. Bachman the initial fusion of the materials takes place as high as twenty-five feet above the tuyeres. It seems likely that in furnaces on Lake ores this height is more likely 15 to 20 ft., but leaving aside this detail the fact that slags form in a broad way as described by Mr. Bachman cannot be too strongly emphasized. The furnace does not make initially a clean iron-free slag of the final composition which we tap out, but following the law of most metallurgical operations it makes first of all a slag to suit itself, that is the most fusible one which can be produced from the ingredients present.

Oxide of iron lowers the melting point of lime-silica slags by several hundred degrees, and these are, as Mr. Bachman states, of the general nature of mill cinder, although probably considerably limier than that material. We never see anything of this intermediate slag when the furnace is in normal operation, but when it is in trouble and without sufficient heat in the hearth to furnish the reducing action we obtain from it to our sorrow slags of various and sundry descriptions, some of them thin, flowing almost like water at temperatures literally hundreds of degrees below the running temperature even of charcoal slags, and yet with so little reserve of heat above their melting point that the liquid surface can hardly be seen for the scull which freezes over it instantly when it strikes the air, and a hand-ladle dipped into such a slag for a sample will come out with a heavy crust instantly frozen on its surface, not tough or pasty, but sharp and brittle almost like ice, and as black as pitch itself.

These slags have compositions varying over a very wide range, but the most fusible one that I have ever seen contained a large percentage of iron, something like 35% FeO . In normal operation probably there is not in the zone of initial fusion sufficient unreduced iron to form a slag of this composition, but there is enough to form one of the stiffer and more plastic and more infusible slags such as we sometimes obtain from a furnace when it is limed up, that is, when the fusion point of the slag has been raised so high by excessive lime that there is not enough heat above its running temperature to give it complete fusibility or to remove all the iron from it, it is probably such a slag as this which first forms in the upper portion of the pasty zone. All the observations which we have of the slag from furnaces in normal operation, but taken from above the tuyeres, are of this general character, tough and black, proving the presence in them of some iron still unreduced. This, for instance, is the character of the slags which drip down from above when we are changing tuyeres and coolers or the like.

It is well to note how completely this physical evidence of unreduced iron in the hearth of the furnace agrees with the deduction in the article on thermal principles that the final reduction of the iron is not accomplished until it descends into the bosh. We have here a conclusion reached upon theoretical grounds, born out by all the objective evidence available.

In considering the matter of slag formation there are several points of much importance to be borne in mind. The first two are those mentioned in the article on chemical principles. First, that the formation temperature of slags is generally higher than their fusion temperature which is almost a corollary of the fact that the fusion temperature of the ingredients is far higher than that of the slags. Second, that the fineness of subdivision and intimacy of mixture of the different ingredients has a pronounced effect upon the formation temperature; as it is almost obvious that it should in view of the first condition.

In addition to these it must be noted that in coke practice a very large proportion of the total silica to be fluxed comes from the coke. In most Lake ore practice this probably amounts to about one-half, the other half coming from the gangue of the ore. Now no matter how intimately the flux and the ore may be mixed the lime must be in great excess at the top of the bosh because approximately one-half of the silica contained in the coke is locked up securely therein and is not all exposed to the solvent action of the slag until the coke has all been burned away which as we know does not take place until it reaches the tuyere zone. It is obvious, therefore, that we must have a much limier and therefore more infusible slag at the top of the bosh where the temperature is relatively low than we have in front of the tuyeres where the temperature is at its maximum. Considering the extremely stiff and pasty nature of these excessively limey slags, judging by the occasional ones which we get from the furnace, it is not a matter of surprise that the zone of incipient fusion should be a pasty zone, but rather that it is not a much pastier one, as in fact it probably would be were it not for the presence of the considerable percentages of iron oxide with its strong action in lowering the melting point.

With those classes of ores which contain an excess of lime such as the hard red ores of Alabama we have a somewhat different condition in respect to slag formation than that which exists with ores containing roughly the same amount of silica per unit of iron, but which require to be fluxed by the use of limestone additions. In the first case the lime and silica of the ore are in very intimate contact, and therefore the formation of the slag is greatly promoted, whereas when the silica is in intimate association with the iron alone and must be fluxed by separate lumps of lime derived from the limestone, the tendency is for the silica to unite with the iron in its partly reduced condition and carry it out of the furnace as a black slag, and either more time or more heat must be provided to obtain equally complete reduction in the latter case. This probably accounts for the fact that the soft red ores of Alabama, having virtually the same ratio of silica to iron as the hard ores, are much less desirable in the furnace. Either slower driving or more fuel is required in exact accordance with the above reasoning, for which I am indebted to Mr. W. L. Kluttz.

IMPREGNATION OF THE FUEL WITH SLAG

In connection with the necessity for reasonable fluidity on the part of the slag it may be as well to call attention here to a curious fact of practice which, if it has been observed, has at least not been the subject of any published comment of which I am aware.

Several years ago seeing a pile of carefully screened slag which had been lying in the weather for some time I noticed scattered through it several pieces of material which looked like coke except that instead of being black they were rust-colored, and when picked up were found to be very heavy, perhaps twice the weight of coke. The question as to what this material might be was discussed between the manager of the plant and myself with much interest. Finally we broke open one of the lumps and found that it was coke impregnated with some other material. Mr. B. G. Klugh was chemist of the plant at the time and on being called in he ground up and polished a broken face of one of these specimens; examination immediately showed that a great percentage of the cell spaces, even in the very center of the original lumps, was impregnated with slag. Subsequent investigation at other plants showed that all the coke which came from the tapping hole and had therefore passed through the hearth, was in this condition. In some cases particles of iron as well as slag were found in the center of the pieces of coke. It was noticeable that this slag was always milk-white, irrespective of the slag which the furnace might be making at the time.

When I first began to operate a charcoal furnace I noticed on the casting cinder little piles of coarse fibers about like white horsehair, the individual fibers two or three inches long, and not lying crisscross but parallel as if they had come done up in a neat package. I asked what caused this but obtained no satisfaction. A short time after, however, coming past soon after cast, when the cinder was still hot, I noticed pieces of charcoal with a white appearance around their ends in various stages of very slow combustion, no flame, merely a quiet dull red glow hardly visible, by which the carbon was slowly passing away. Closer examination showed that the white appearance at the ends was due to the projection of fibers projecting from the cells, and presently it became evident that the neat little packages of "horsehair" were fibers of slag cast absolutely perfect into the cells of the coal in the hearth, and exposed by the slow burning away of the charcoal as it lay on the hot slag in the open air. Analysis of this material proved it to have the same composition as the main body of the slag made at the same time.

The extreme whiteness of the slag in both these cases is an index of the completeness with which the iron oxide is reduced and removed from it, and suggests the possibility that this extraordinarily intimate contact between the slag and the fuel may be a factor of some practical importance in the final completion of the smelting operation, and certainly it is a factor which can not exist except with a reasonably fluid condition of the slag.

THE ZONE OF FINAL OPERATIONS

This is the region of highest temperature in the furnace extending from a short distance above, to just below, the tuyeres. In it the slag attains its final composition, the coke having all burned away and released the slag-forming ingredients which it contains, while the intense heat suffices, in a proper-working furnace, to deoxidize the last remaining portions of the iron and causes them to enter the iron bath leaving a slag which in good practice contains only two or three tenths of 1 per cent of iron.

In coke practice, owing to the fact that the slags used are on the lime side of the most fusible ratio of lime to silica, additions of silica cause the production of a more fusible slag, hence the release of the silica from the coke ash, and the increase in temperature, owing to the conditions in the region, both contribute to make the slag more fluid. As we have many times re-

iterated, the critical temperature of the furnace not only in the theoretical sense of that word but in the actual sense that the operation of the furnace depends upon it, is that temperature at which the slag becomes sufficiently fluid to free the remaining traces of iron, both shot and oxide, which it contains, and sufficiently mobile to cover the coke and carry away practically all the sulphur it contains, as fast as the latter is disengaged, thus keeping all but small traces out of the iron.

We see, therefore, that the slag has only to reach this condition in its final stage, but it is absolutely essential that it be reached, if not, evil consequences will follow very rapidly. First, the sulphur is no longer sufficiently absorbed by the slag, and deleterious quantities enter the iron lowering its value and finally reducing it to a non-merchantable commodity. Simultaneously with this begin considerable losses of iron carried off with the slag, sometimes as shot, more often in the form of ferrous oxide dissolved in it, and finally as an inextricable mixture of bad iron and bad slag which do not separate instantly with a clean line of parting like oil and water, but which, partly for physical and partly for chemical reasons, remain mixed together if not dissolved one in the other.

Following these conditions, the slag becomes too stiff to be flushed from the furnace through the ordinary opening of one to two inches in diameter, and the water-cooled monkey through which this operation is performed must be removed bodily making a hole some 6 to 10 in. in diameter through which the slag will flow unless the furnace is lime-set or in serious trouble from lack of heat. "Lime-set" was a term used principally by the furnacemen of an older generation, before the simple principles of furnace burdening were as well understood as they are now, to describe the condition to which furnaces were not infrequently brought by the addition of more and more lime to accomplish certain results in the kind of iron produced, or through a misunderstanding of some abnormal condition of the furnace and attempting to correct it with what turned out to be an overdose of lime.

The fusion temperature of slags with increasing lime content goes up with great rapidity, and after a certain point is reached the free-running temperature of the slag becomes higher than any temperature obtainable within the hearth of the ordinary blast furnace, with the result that the slag cannot be removed, and if the furnace continues to be blown this infusible slag rapidly builds up in the hearth and bosh making it more and more difficult for the blast to penetrate from the tuyeres up through the stock column until finally the hearth and bosh of the furnace are almost filled solid with this excessively limey material, which when it is exposed to air or cooled off, not infrequently breaks down much like slacked lime.

In charcoal furnaces occasionally we reach a similar condition from a cause exactly the opposite since slags containing a great excess of silica while they are not as infusible as those containing a similar excess of lime, are extremely stringy and viscous, with the result that at the comparatively low temperatures of the charcoal furnace they may build up on its walls almost as badly as do excessively limey slags in the coke furnace. But the temperature range through which they may be made to flow, even if slowly, is wider than in the case of the limey slags, and charcoal furnaces are therefore not so liable to become completely "bunded up" in the expressive language of the furnace man, from this cause as were coke furnaces a few years ago.

In this zone important changes occur in the iron it-

self. We have already seen that the silicon and phosphorus can only be reduced in the presence of incandescent carbon at the highest temperatures obtainable in the furnace, and when the iron is present to absorb them. The same thing is true of the manganese in a less degree. That is to say, a furnace charged with an ore of phosphorus or silicon without iron would not reduce any of those materials, and a blast furnace operated in the ordinary way charged with manganese ore without iron would reduce little or none of that element, although by material changes from regular iron furnace practice it can be made to do so. In order then that these elements may be reduced, it is necessary that the iron be present as such so that its affinity for them may assist the action of the incandescent carbon and the high temperature in reducing them from their oxides.

These actions, therefore, go on exclusively in the hearth. It is probable that a large portion of the carbonization in the iron also goes on at this point because it is quite difficult, by any other process, to make iron absorb as much carbon as the product of the blast furnace ordinarily contains. Even the electric furnace with its enormous temperature has found some difficulty in securing the conditions which would give the carbonization of iron necessary to constitute real cast iron, while other methods of melting have generally not been able to raise the carbon much, if any, above 3 per cent.

In the hearth of the furnace we have the condition that iron is subdivided into extremely small streams, trickling down over incandescent coke, in an atmosphere as reducing as it is possible to produce, and at the highest temperature of the furnace. Under these conditions the completion of the carbon absorption takes place.

As to how much carbon is absorbed in the regions above this we do not know. We do know that iron exposed to intimate contact with fine carbon over long periods of time and fairly high temperatures, absorbs 1 or 2 per cent of carbon, and when the ore is of a nature to produce the deposition of carbon dust from the gas upon itself, we have the conditions under which carbonization may easily take place, but so far as I know no determinations have ever been made as to the extent of this action.

In addition to these, other actions go on in the hearth, and some of them we find it extremely difficult to account for. One of the most notable problems is the composition of the salamander taken from the hearth when the furnace is blown out. Salamander is a term covering literally a multitude of sins.

The salamander of the old-fashioned charcoal furnace consisted of what geologists would call "pudding stone," of charcoal slag of all colors and compositions, interlaced and tied together with a stringy or sponge-like mass of iron.

In coke furnaces we find masses not unlike this in general characteristics except that imbedded coke is rare, and the iron portion of the structure is less sponge-like. The intimate mixture in this case is of iron, slag, graphite, and sometimes firebrick, but in the center of the coke furnace we usually find a depression well below the level of the original brick hearth of the furnace filled with iron, which, below the surface, is quite unmixed with slag. The body of solid iron varies much in size and is generally very graphitic around the edges, but frequently extremely dense and solid in the center. Sometimes this mass consists only of the frozen pool of metal last formed in the furnace which could not be removed from it because of its depth and of the absence of a sufficient blast pressure to lift it out through the tapping

hole. But usually in addition to this there is another mass below it, and generally quite distinct from it, which likewise consists of solid iron, but whose composition bears apparently no relation whatever to the composition of the iron made during any portion of the blast. For instance, it is well known that the affinity of iron for phosphorus is so great that practically all the phosphorus introduced into the charge is taken into the iron, yet these salamanders often contain only a small fraction of the phosphorus contained by the iron made during the blast. The manganese is generally low, the silicon also is quite low, and the carbon which in cast iron runs practically always from $3\frac{1}{2}$ to $4\frac{1}{4}$ per cent; I have seen in one of these salamanders down to about 1.5 per cent.

This material was really a poor grade of high-carbon steel of which the crystals were distinctly bent when the broken faces were slid over one another, and of which a piece taken to the blacksmith's shop could almost, but not quite, be forged.

I am advised by John M. Reese that he has had a practically identical experience.

Comparing the analysis of such a material with the pig iron from which it has presumably been produced, we can only reach the conclusion that there has gone on here a slow but none the less effective oxidizing action at the bottom of the bath although cut off from access to the blast by a layer of iron or slag, or both, and at cast time when the hearth is relatively bare, covered by a mass of coke several feet in depth below the tuyeres, conditions apparently precluding any possibility of access to this region by the oxygen of the blast.

The cause of this peculiar action is not fully understood as far as known to me, but it is impossible to resist the conclusion that the oxidation must be carried on by slag not completely reduced; of the kind which we always find trickling down the walls whenever we have occasion to investigate conditions.

It would seem necessary to suppose that oxygen in this form is carried down into the hearth, that it is cut off from the reducing action of the coke column by the fact that the latter is in part floated on the surface of the charge as described in a previous article, and that this slag which is known to be a very active oxidizing agent satisfies its desire for oxygen at the expense of the metaloids in the plastic but not quite fluid mass of iron in the bottom of the furnace.

The mechanism by which this action is carried out I do not pretend to understand. If anyone will work it out and publish the results he will satisfy the acute scientific curiosity of a great number of his professional brethren by so doing.

The Asphalt Primer and Colloidal Catechism is a little pamphlet issued by the Barber Asphalt Paving Company of Philadelphia. It is an exceedingly clever piece of propaganda, interestingly written and catchingly illustrated. It starts with ancient road construction, going back to King Cheops and the Via Appia of the Romans, compares ancient and modern road construction, and deals with asphalt and its function in a paving mixture. The fact that Trinidad Lake asphalt contains colloidal matter is emphasized and simple explanations are given of such terms as colloids, surface energy, and adsorption; and what they have to do with paving mixtures. In a most skilful manner the non-suspecting lay reader is led to absorb some highly modern chemistry and the primer winds up with a tribute to colloidal chemistry for placing the formulation of paving mixtures on a scientific basis and for accounting for the established excellence of Trinidad lake asphalt.

Liquid Chlorine*

BY DR. G. ORNSTEIN

All are familiar with the element chlorine—its history, manufacture and characteristics—so that it will be hardly necessary to go into details on this subject.

CHEMICAL PROCESSES FOR PRODUCING CHLORINE

The first process employed commercially was the same which we have all used as students in the laboratory—namely, that of generating it from manganese and acid, which may be either muriatic or a mixture of salt and sulphuric acid.

This process was made eminently practical later on by Weldon's invention of recovering the manganese by means of addition of lime to the waste liquor, blowing air through the mixture, and returning it in this regenerated form to the process. This Weldon process is the only purely chemical process operated on a commercial scale, which has furnished a chlorine gas of sufficient concentration to be used for liquefaction. The Deacon process in which hydrochloric acid fumes are decomposed in the presence of air and a contact substance, such as copper chlorides, yields a weak gas which is not practicable for the purpose of liquefaction—at least not directly.

To overcome this drawback in this process and in other instances where a weak chlorine gas is obtained, several processes protected by patents have been worked out, particularly by Goldschmidt and Sperry, which aim at absorbing the chlorine from a weak mixture, the former by stannic chloride, the latter in the form of chlorine hydrate, thus separating it from the diluting impurities and later on decomposing it again by application of heat for the purpose of producing pure chlorine. In the Acker process, in which an extremely poor gas was obtained, one went even so far as to first convert the chlorine into bleaching powder and subsequently decompose it by acid.

However, it seems that none of the chemical processes are operated any longer for the purpose of liquefaction, except perhaps in a few individual instances, and the chlorine liquefied nowadays, in this country as well as abroad, is almost entirely produced by electrolytic processes.

ELECTROCHEMICAL PROCESSES FOR PRODUCING CHLORINE

The electrolytic decomposition of brine or muriate of potash is well known in principle. It consists in passing an electric current of high amperage through an electrolytic cell, in which the anode is made of carbon, or what is much to be preferred, Acheson graphite, or fused iron oxide, while the cathode consists of iron, either in the form of a perforated sheet or wire screen, or in some instances a solid sheet depending on the details of construction.

When the electric current is passed through the cell the brine is split up into its components; chlorine will escape at the anode and caustic soda or caustic potash will be produced at the cathode. The products of electrolysis have to be kept apart, as otherwise they will combine, forming hypochlorite and eventually chlorates, and quite a number of constructions have been devised and patented to prevent this re-combination. In the larger number of constructions diaphragms of various designs are employed—for instance, in the Gibbs, Townsend, McDonald, and Billiter cells the basis of the diaphragm being mostly asbestos. In others they are kept apart by gravity and by causing a constant flow

*A paper presented at the meeting of the American Electrochemical Society (N. Y. Sec.), on February 11, 1916 (in joint session with the New York Sections of the American Chemical Society and the Society of Chemical Industry).

of liquid in the direction from the anode to the cathode. This principle is employed, among others, in the "bell process."

A third principle is employed in the mercury cell, in which the cathode is formed by mercury instead of iron, absorbing the sodium or potassium under the influence of the electric current, and this in turn is released again by water outside of the electrolytic cell in the form of caustic. The pure mercury is then again returned to the cell and reloaded at the cathode—but no matter of what construction the cell may be, in all instances a highly concentrated chlorine can be obtained which, with graphite or iron oxide anodes being less subject to electrolytic oxidation than carbon, should easily yield gas of 97 to 98 per cent purity, the balance being carbon dioxide, electrolytic oxygen and a slight trace of air. With iron oxide electrodes, of course, no carbon dioxide can be formed, but the amount of electrolytic oxygen will be correspondingly higher. However, only in a few cells a gas of this purity is actually obtained, on account of mechanical defects, such as leaks in the cell covers or pipe lines, or negligence of the cell attendants.

LIQUEFYING CHLORINE GAS

For the liquefaction of chlorine it is of great importance that attention should be paid to generating a highly concentrated gas, because otherwise the percentage which can be liquefied from a certain volume of chlorine will decrease rapidly with each per cent of impurities.*

The balance, which still contains between 55 and 65 per cent of chlorine, is called blow-off gas and is released from the liquefying machinery, from time to time, when the pressure exceeds certain limits. It is generally conveyed to the bleach chambers; this is the preferred way of both using and getting rid of it, as on account of its dilution it can be used only for a limited number of other purposes.

In any case absorption capacity of some kind has to be provided for, and it therefore appears that a chlorine liquefaction plant can be operated to advantage only in connection with the manufacture of other chlorine products.

HISTORY OF LIQUID CHLORINE

A great many attempts have been made to liquefy chlorine ever since the beginning of the nineteenth century, but until recently they were largely confined to laboratory experiments without any practical value.

The first liquid chlorine was obtained in 1805 by Northmore, and as early as 1823 Faraday demonstrated the well-known experiment which is found in every text book, namely, the decomposition of chlorine hydrate in a sealed and bent glass tube, the hydrate being heated in one branch of the tube and the escaping chlorine being liquefied in the other branch, which is cooled in a freezing mixture. But until after 1880 nothing had been done which could justify any hope of success for working out a commercial process.

Between 1880 and 1890 a number of processes were worked out which at least made an attempt to produce liquid chlorine on a commercial scale. For instance, Vautin attempted to compress chlorine gas by pressing air into tanks containing chlorine and at the same time cooling it down to a low temperature.

Others, for instance Hannay and Marx, based their processes on the decomposition of chlorine hydrate in a closed vessel. Heinzerling attempted to reach his object by first compressing chlorine, cooling it to a low temperature and then liquefying it by sudden expansion.

But none of these attempts were successful and commercial liquid chlorine remained an unrealized dream until the arrival of the process of Knietsch, of the Badische Company, who in 1888 placed the first liquid chlorine on the market. He was the first to realize that it was of fundamental importance for the commercial liquefaction of chlorine that chlorine be used which is at once highly concentrated and free from moisture—two points which the former inventors had overlooked. He also found that chlorine carefully dried did neither attack iron nor a number of other metals employed for building commercial machinery, and through an ingenious device of a so-called liquid piston he was able to put the chlorine under a high pressure without any danger of leaking through the stuffing box around the piston, causing corrosion, etc., For the liquid media he used a column of petroleum around the piston, and below this and in the other branch of the U-shaped cylinder he used concentrated sulphuric acid. The liquid piston was lifted up and down by a plunger moving in the petroleum and thus sucked in and compressed chlorine gas which through a separator was carried on to a condenser where, under the influence of low temperature, it liquefied and was then filled in to the shipping containers.

He also heated the sulphuric acid by a steam or hot-water jacket in order to reduce the absorptive power of the acid for chlorine gas.

According to my knowledge most processes which are now in operation are still based on these fundamental principles. That is, all of them are using a liquid for compression, and while they may have been simplified in some way, for instance by omitting the petroleum and not heating the sulphuric acid or by making changes in other directions, compressing the chlorine by entrainment, or in two or three-stage compression, yet in almost every case the principle has been maintained.

There are several processes on the market, for instance that of the Linde Company of Germany, by which liquefaction is effected simply by cooling to -45°C . or below, without any pressure. But the drawback of this process is that the percentage liquefied is lower throughout than that obtained with the combined system of compressing and cooling.

Regarding the relative merits of the various processes I must hesitate to express an opinion. There is so much secrecy observed in this field, as in all lines of chemical industry, that I do not know enough about the details of construction and operation of most of the other manufacturers to warrant my passing comparative criticism on this subject.

In one point I feel "the people who know" will agree with me—stick to what you have got and have tried out in the course of years and of which you have studied all the little knacks and moods and—never mind what excellent results the other fellow "says" he gets. I would rather hunt for trouble in a twelve-cylinder automobile motor than tackle a chlorine compressor when it is in the mood of the "morning after the night before."

The liquid chlorine is shipped in steel cylinders containing about 100 lb. net and of a tare weight of 70 to 100 lb. In large quantities it is also shipped in tank cars. The pressure in these containers varies with the temperature from about 70 to 100 lb. per square inch at ordinary temperatures. But the pressure will drop rapidly on account of the heat consumed by evaporation if chlorine is drawn off continuously even in relatively small quantities.

In one place where chlorine was drawn off continuously for the purpose of water sterilization at a room

*The author showed curves illustrating the influence of concentrations as well as of pressure and temperature.

temperature of about 2 deg. C. the pressure dropped in 24 hours from around 55 to 15 lb., although not more than $\frac{3}{4}$ lb. per hour were taken from a set of four cylinders, or 3 oz. per hour per cylinder. This cooling or freezing action can be easily counteracted by playing steam on the cylinder until the frost which will form has disappeared, or by placing it in a tub with warm water or in a cabinet which is kept warm by artificial heat or similar means.

LIQUID CHLORINE IN THE UNITED STATES

In this country commercial liquid chlorine was unknown until the year 1909. There had been imported prior to this date quantities of liquid chlorine from Germany, but these were used solely for experimental purposes on a more or less extensive scale, but the United States did not begin any manufacture until 1909.

It was in the beginning of this year that the Electro Bleaching Gas Company, after about two years of experimenting, erected the first compressors, and a short while later two more chlorine concerns started in operation, the Goldschmidt Detinning Company and the Castner Electrolytic Alkali Company. The former one used the product largely for its own purposes, namely, the detinning of tin scrap, whereas we had to find and build up a market for this entirely new product.

The two most important fields to which the liquid chlorine was to be introduced were the bleaching of vegetable fiber, such as cotton, flax and paper pulp, and chlorination of all kinds, such as ores, organic compounds, pharmaceutical products, etc.

Above all, we found it necessary to instruct our purchasers how to use the liquid chlorine for their various purposes, and we still recall with considerable pleasure the many comical occurrences which happened at that time. In one textile mill our friends apparently thought the cylinder contained something like a liquid bleaching powder which they had been accustomed to use for generations. So they simply attached a hose to the valve outlet and tried to empty the cylinder into a vat containing water for diluting to proper strength and then they opened the valve. The result may be easily imagined. After a minute or two there was nobody left in the mill who could be induced to enter the place and shut off the valve. The letter we received was all but complimentary. Many other episodes of a similar nature occurred.

Therefore, before we could market the product we had to instruct our purchasers how to use it, and we were compelled to make demonstrations of how to prepare the bleach liquor and how to bleach yarn with it in one mill after the other. Finally we succeeded in convincing a number of the largest and most conservative mills of the decided advantages of liquid chlorine as compared with bleaching powder, and these mills for the past four or five years have definitely abandoned the bleaching powder in favor of the liquid chlorine.

BLEACHING SOLUTIONS MADE FROM LIQUID CHLORINE AND BLEACHING POWDER

At the beginning we had to convince many chemists that the amount of available chlorine present in a bleaching solution prepared with liquid chlorine and alkali, for instance soda ash, was equal to the full amount of chlorine passed in. They were basing their objections on the formula:

they insisted that these equations proved that one-half of the chlorine was converted into NaCl and thus wasted for bleaching purposes.

The assumption was that in bleaching powder the available chlorine was present in the form of a CaOCl_2 . As a matter of fact this is the most accepted formula for the powder, so that the impression is given as if all the chlorine present were in the available form; but upon dissolving this will be split up according to the equation,

so that one-half of the chlorine is converted into the chloride and the titration with As_2O_3 proceeds according to the formula

Thus it can be seen that the so-called available chlorine does not represent the actual amount of chlorine present in the hypochlorite, but only one-half of it, and is rather an expression for the available oxygen in the same compound which if expressed in chlorine value must, on account of the bivalency of the oxygen and the monovalency of the chlorine, naturally have twice the chlorine value.

It now follows from comparison of the above equations that the chemical reactions of bleaching powder solutions and solutions made with liquid chlorine and alkali are identical, and the fact can no longer be astonishing that if liquid chlorine is used for the manufacture of bleaching solution, an available chlorine content is obtained substantially equal to the number of pounds of chlorine absorbed by the solution.

We were able to show—and in connection with this wish to acknowledge the valuable assistance rendered us by Dr. J. M. Matthews—that bleach solutions thus prepared gave decidedly better results than bleaching powder. We could demonstrate that only one-half of the amount of available chlorine and even less is required to be present in order to give the full bleaching results which formerly had been obtained with chloride of lime, while the tensile strength of the goods is correspondingly improved.

A large reduction of the so-called sour, namely the use of weak sulphuric or muriatic acid after the bleaching bath for the purpose of destroying the last traces of residual chlorine, represented a further improvement in this important respect. The explanation for the increased efficiency seems to be that in case a bleach is used in which the chlorine has been combined with soda ash the presence of free hypochlorous acid causes a more rapid and more efficient action on the fiber than the neutral calcium hypochlorite. In addition any bleach prepared with soda as a basis and with entire absence of lime salts seems to have a higher penetrating power on the cloth on account of no substances being present which are capable of forming insoluble precipitates on the fiber. This theory is substantiated by the observation that a hard twisted yarn or cloth requires less available chlorine as compared with the necessary quantity of bleaching powder solution than a material of a looser texture.

OTHER ADVANTAGES OF LIQUID CHLORINE

Another large field in which liquid chlorine is now used extensively is for chemical chlorination processes, in which the quantities consumed are not large enough for warranting the concern to build a branch factory near the chlorine-producing concern for receiving the gas directly from the cells, so that the use of liquid chlorine, which is easily transportable, is the only other choice.

A number of manufacturers have tried to make the chlorine themselves from either bleaching powder and acid or manganese and acid, but in most instances they have found that it was much more to their advantage to purchase liquid chlorine ready made. The reason is

not only the cost of the raw materials, which in either case exceeds the price at which liquid chlorine can be purchased, but there is also the advantage of the liquid chlorine being absolutely dry, chemically pure, and under a pressure sufficiently high to be easily conveyed to any point of application and pressed through liquids to be treated without the troublesome medium of blowers, fans, pumps, etc.

The valve of the chlorine cylinder, also, permits of an easy and accurate regulation, whereas the above-mentioned chemical processes when once started cannot be regulated at will unless a gasometer is used in connection with them; this only introduces another source of trouble because as the only sealing medium concentrated sulphuric acid must be employed.

Of the advantages just cited, its purity is one of the most conspicuous characteristics of liquid chlorine. When a fresh cylinder is opened it will usually yield at once a gas which is 96 to 98 per cent pure, and after several pounds, from 3 to 5, have been taken out, it goes up to 99 per cent, and after another pound or two it will be at 99.7 and 99.98 per cent, and will stay there until the last drop of liquid has evaporated from the cylinder. In view of these figures, which can be easily substantiated at any time, liquid chlorine may justly be called one of the purest, if not *the* purest, chemical on the market. The initial slight amounts of impurities represent the small left-over traces of air, etc., which were in the gas coming from the cells.

LIQUID CHLORINE FOR WATER STERILIZATION

A third large field for the use of liquid chlorine has been opened up during the last three years, namely its use for the sterilization of city water supplies and sewage. In this field as well as in the bleaching industry liquid chlorine had to compete with its old competitor, bleaching powder, but we are proud to say that it has made a pretty good showing, even without making allowance for its youth and for the lack of experience.

After some experimental work had been done previously the first commercial machines were installed in the Western New York Water Company plant at Niagara Falls, N. Y., in November, 1912, where we received valuable assistance from F. H. Huy, general manager of the Western New York Water Company's plants, and in Wilmington, Del., in January, 1913, where they are still in continuous satisfactory operation. These machines are based on the principle of absorbing a measured quantity of chlorine in a small amount of water and subsequently adding this solution to the water to be treated. This so-called absorption process has the advantage of an even and rapid distribution of the sterilizing agent throughout the whole body of water. This advantage is particularly apparent in large installations, such as the Torresdale filter plant in Philadelphia, where from 220,000,000 to 330,000,000 gal. of water are filtered daily.

It is furthermore of advantage in plants in which the water to be treated is under high pressure—which in some places exceeds the pressure of the liquid chlorine itself. In these installations the application of the chlorine in the form of a solution which is forced into the main by means of a specially constructed pump is the only form in which the problem can be solved.

In the field of water sterilization the Leavitt-Jackson Engineering Company is deserving of particular mention on account of the original principle involved, which consists of feeding the chlorine into the water by weight by a balanced beam construction acting on the chlorine feed valve. This is an excellent construction mechanically, but not sensitive enough for the minute quantities

of chlorine which are required by far the largest number of water works.

The principle used in our first machine comprises the pressure regulation by a reducing valve or by two switched in series, the measuring of the rate of flow by the pressure difference on both sides of a calibrated orifice caused by it, and the subsequent absorption of this measured quantity in water prior to its addition to the main flow of water.

Under the conditions in which the chlorine in the absorption tower is discharged against atmospheric pressure it is unnecessary to connect the U-tube to the down-stream side of the orifice, as would have to be done were the chlorine to be discharged against pressures higher than atmospheric.

We are also using a rate of flow meter for measuring the chlorine.

Through constructions along these lines it has been possible to effect an accurate regulation of chlorine gas to any quantity as small as 1/40 oz. per hour and as high as 25 lb. per hour, irrespective of any variations of the pressure in the cylinder, which in the course of operation may drop from 100 to 15 lb. without influencing the rate of feed.

To realize thoroughly the importance of employing a sterilizing agent which can be added under perfect control as to its quantity, it is sufficient to point out that it is necessary to add it to a continuously flowing stream of water and that it has to be mixed and intermingled with it continuously, thoroughly and evenly. This is not possible with chloride of lime, because the devices used for this purpose, such as orifice boxes, etc., will after a short time be partly or entirely plugged up by a lime deposit and will be in full working order only for a few days at a time. We have also succeeded in developing apparatus capable of automatically varying the amount of chlorine added in proportion to the rate of water flow.

Further advantages which may be cited in favor of liquid chlorine are: absence of taste and odor in limits very much wider than those prevailing for bleaching powder—no sludge or dust—smell or other nuisance, and particularly its *efficiency*, which is two to three and one-half times as high as the same amount of available chlorine present in bleaching powder. In other words, 1 lb. of liquid chlorine has approximately the efficiency of 6 to 10 lb. of chloride of lime.

In these various directions we had first to overcome considerable prejudice on the side of the communities, particularly as regards taste and odor. To what extent prejudice may sometimes run away from common sense may best be learned from the fact that complaints about chlorine taste and odor came pouring into the office of the Board of Health in Buffalo—four weeks *before* our machines were installed.

The results obtained by this process and applied by these machines have been highly satisfactory, as can especially be gathered from the Board of Health records of the various communities which in cities which formerly had an exceedingly bad record for typhoid fever are now reported as being almost or entirely free from it, and in no case, wherever typhoid fever then occurred in such a community, has it been possible to trace it back to the water used, but the reasons were always found in causes other than the city water supplies, such as milk, impure food, etc.

LIQUID CHLORINE AND THE WAR

This evening's papers deal with electrochemical war supplies and I, therefore, have to devote some space to the use of liquid chlorine for war purposes.

The war has naturally had considerable influence on

the liquid chlorine trade, though the causes are entirely different from those which are responsible for the demoralization of prices of other chemicals.

For the latter the present situation is caused simply by the fact that they were hitherto imported from abroad and only small quantities, if any, manufactured here. Now the supplies being entirely shut off, prices, of course, have gone sky-high. Liquid chlorine, on the other hand, is a domestic material which, therefore, could not be influenced by the shutting off of imports as to the quantity available. The increase in the trade and the price of liquid chlorine must principally be traced back to the shortage of bleaching powder, of which formerly more than 50 per cent was imported, and on account of it being shut off its price has risen from about \$23 per ton to figures between \$200 and \$300, whereas the price of liquid chlorine has only increased from \$160 or \$200 per ton to \$240 or \$300. Taken in figures of available chlorine, which is the compound by which, apart from other considerations, the comparative values of the two materials are measured, this is now worth in bleach containing 35 per cent available chlorine \$570 to \$860 per ton, whereas in liquid chlorine, which can be almost quantitatively converted into the available form, it can be purchased for no more than the price of the liquid itself.

How long these conditions will continue to prevail is hard to say. Several of the big manufacturers are enlarging their plants and their bleach capacity, which may relieve the present shortage to some extent, but hardly enough to reduce prices to anywhere near normal. The enlargement of plants, however alluring, is carried out very conservatively, realizing that after re-establishment of peace the imports will begin again from Europe, particularly Germany and England, perhaps not immediately, as some assume, but soon after.

In the meantime the price of liquid chlorine may still travel a long way upward before approaching the present value of available chlorine in bleaching powder.

Due to this condition, namely, a price enormously higher for bleach than for liquid chlorine, manufacturers have been much tempted to divert part of the chlorine from the liquefying machinery into the bleach chambers, and a certain stringency may have been caused by this, as well as by the exportation of moderate quantities for war purposes.

From the reports we have received from the other side, liquid chlorine as such has been used as a weapon for incapacitating the enemy. To what extent these reports are strictly true and what part liquid chlorine as such has played in it, we do not know.

I have read only one report in one of the medical journals which seems to be entirely unbiased and therefore in fair accordance with the facts, free from newspaper sensationalism.

The report shows more or less severe affections of the breathing organs, so severe in some instances that it seems incredible, according to my experience, that they should have been caused by inhaling of chlorine gas. Of course, I do not doubt that chlorine can be very detrimental to the human system in a closed room, from which there is no escape, but in the open air with a wind blowing, no matter how gently, it seems next to impossible that any suffering beyond that of temporary coughing spells, vomiting, etc., could occur.

It has been suggested from various sides, and it is undoubtedly a fact, that the chlorine if employed is mixed with other ingredients, such as bromine, sulphur and others, which would cause more severe and more lasting irritations than chlorine alone. I know personally of one instance in which sulphur has been used in connection with liquid chlorine.

We naturally have had a long experience in this line, particularly at the start, when we had to struggle with a good many imperfections, leaks, etc., and never in any instance have we seen any lasting detriment suffered by any of our men.

I have also had several years' experience in Germany along the very same lines, and there also I have never been able to observe one single case of this kind. To appreciate this statement fully you ought to see into what kinds of atmosphere our men had to go sometimes without using any protection whatsoever, and when they had swallowed half of our production and were coughing violently they took a drink of Rexalls' A. B. C. seltzer or bromo seltzer and a few minutes later were back in the plant. These compounds, as well as any other of a stimulating or nerve relaxing influence, seem to be the best antidote for chlorine—among them a good stiff drink of whiskey.

If these are not available, inhaling of alcohol, chloroform or tetrachloride of carbon vapors spread out on a handkerchief will give speedy relief, but with the two latter ones one should be careful so that no narcotic effect may take place.

The inhaling of ammonia, which is recommended in several text books, should be absolutely rejected, because in most instances the irritation grows only worse instead of better.

Prevention is better than a cure, and the best prevention of inhaling too much chlorine is not to be afraid of it, and if a whiff of it gets into the nose, not to stop breathing abruptly. If you do and if you cannot get out of the room before you have to breathe again, you are bound to take a deep breath which will carry the chlorine to all the tender parts of your lungs and a violent coughing spell will be the result.

If, on the other hand, you continue to breathe—lightly, without taking a deep breath—you can stand a pretty strong chlorine atmosphere for minutes at a time, without any muzzle, safety helmet or other protection. Be careful, however, not to inhale the white fumes which are formed by ammonia and chlorine, in the course of trying to locate chlorine leaks with a rag soaked in ammonia. The coughing spells and the effect on the eyes caused by them are very much worse than with chlorine alone and last longer. Also wet chlorine such as emanates from a saturated chlorine water seems to have worse effects than the dry, although only slightly more so.

We have in our plant an oxygen safety helmet, but except for purposes of keeping our men trained in its operation, I have never seen it in actual use.

Another purpose for which undoubtedly quantities of liquid chlorine have been shipped abroad from this country is for the manufacture of picric acid, which, in this instance, can be made by first producing chlorbenzol, nitrating it, and then replacing the chlorine by hydroxyl by treatment with alkali.

These are the two only purposes for which, as far as I know, liquid chlorine has been used for war purposes. However, as you see, they are rather limited in their effects and, therefore, hardly deserving of the prominent place accorded them in the newspapers.

In general, I may say—and I hope I have been able to demonstrate it in this paper—that liquid chlorine is much more important for peaceful than for war purposes, and we are taking considerable pride in the fact that in the past few years we have been able—instead of causing destruction of human lives—to save them from the ravages of typhoid fever and in this way to prove that instead of being an enemy, liquid chlorine is becoming more and more a savior and a boon for mankind.

Recent Chemical and Metallurgical Patents

Gold and Silver

Sodium-Amalgam Precipitant for Cyanide Solutions.

—It is known that metallic sodium may be diluted with mercury so that it will replace various metals from their solutions, the metals thus displaced combining with the mercury. This principle is applied by HANS FOERSTERLING and ARTHUR L. HALVORSEN of New York City, in the patented use of sodium-amalgam for precipitating gold, silver and copper from cyanide solutions. The apparatus designed for applying the invention is shown in Fig. 1. It consists of cylindrical casing 1, of soft steel, an axis 2 bearing an inclosed drum 7 on which, at suitable intervals, are annular soft steel plates 8 having perforations 8a for the passage of solution. In the

The invention provides a cyclic process specially adapted to the treatment of complex sulphide ores containing such metals as lead, iron, copper, silver, gold, etc. The proper performance of the cycle depends on the presence of manganese, which may either be a normal constituent of the ore or added in the form of manganese carbonate or sulphide. The addition may be made either on starting or after the operation has been established. The function of the manganese is to serve as a carrier of oxygen to oxidize ferrous compounds to ferric, and thus make possible the complete separation of iron from solution.

Sulphide ores or concentrates are first roasted. Manganese is introduced subsequent to the roasting operation, and in such quantity as may be required by the ferrous iron to be oxidized. After roasting, the ore is leached with sufficient dilute sulphuric acid so that there is from 5 per cent to 10 per cent excess acid over the amount required to complete the reaction. The oxidized metals go into solution as sulphates, some of the iron as ferrous sulphate. In this state the iron is not removed by adding lime or zinc oxide, and it is for the oxidation of this ferrous iron that manganese in its higher forms of oxidation is used. It may be present in the form of manganese dioxide or permanganic acid and possibly other states of oxidation higher than the manganous. It may be present either in solution or suspension, according as it is soluble or insoluble.

FIG. 1—SODIUM AMALGAM PRECIPITATING APPARATUS

upper part of the casings are pipes 9 and 10 for the inflow and outflow of solution, while pipe 11 serves as an exit for gases. At the bottom is a pocket 12 into which material can be introduced through pipe 13. The axis, drum and attached plates are adapted to revolve through a bath of sodium amalgam in the lower part of the casing, and carry thin films of amalgam upward through the solution flowing through the casing. As the metals are precipitated, cyanide is regenerated. The precious-metal amalgam can then be drawn off through pipe 15, while new supplies of sodium and mercury are added through 13.

Application to the precipitation of silver-bearing solution is illustrated thus: The solution contains 8.5 oz. silver and 0.095 oz. gold, 3.7 lb. free NaCN and 0.5 lb. Ca(OH)_2 per ton. As it passes through the apparatus at the rate of 100 tons per day, it comes in contact with the thin films of sodium amalgam on the plates and silver is displaced from solution and absorbed by the mercury. Sodium is fed at the rate of 90 lb. per day, and silver amalgam is withdrawn at a rate varying from 35 to 350 lb. per hour. Barren solution leaving the apparatus has a gold and silver value of \$0.07 per ton, and contains 4.1 lb. free NaCN and 1.7 lb. equivalent Ca(OH)_2 . The efficiency of the process is 99 per cent, since the gross value of the precious metals in the feed, with silver at 60c. and gold at \$20 per ounce, was \$7. The process is equally applicable to the recovery of copper from cyanide solutions. (1,164,636, Dec. 21, 1915.)

Zinc

Hydrometallurgy of Zinc with Electrolytic Deposition.—An insight into the methods to be used by the Anaconda Copper Mining Co. in the wet treatment of zinc ores and production of electrolytic zinc at Great Falls, Mont., may be had from patents recently granted to FREDERICK LAIST and FREDERICK F. FRICK, of Anaconda, Mont., members of the technical staff of that company.

In any event in these higher states of oxidation the manganese is a product of the final electrolytic stage of the process, and is returned to the proper stage for the oxidation of ferrous iron. Having oxidized all the iron, that metal can now be precipitated by milk of lime of zinc oxide. Iron, arsenic and antimony are thus precipitated. For the removal of copper from the electrolyte, and possibly small amounts of silver, arsenic and antimony also, zinc dust is added to the solution. At the stages of precipitation of the various impurities, decantation or filtration of the solution follows, and finally a pure electrolyte of zinc sulphate is obtained, containing manganese. This solution is then electrolyzed, using insoluble anodes, as of lead, and cathodes of zinc starting-sheets. The products of electrolysis are zinc, sulphuric acid and manganese dioxide and permanganic acid. The solution containing the sulphuric acid and manganese is now available for further leaching, oxidizing the ferrous iron and facilitating its removal. According to a modification, an excess of the roasted ore may be used for precipitating iron, arsenic and antimony; but since ferrous iron might also be added in this procedure, a certain amount of manganese dioxide derived from electrolysis is introduced at the same time. Since the roasted ore is used in excess for this precipitation, a small residue would remain, and this is to be mixed with raw ore in the roasting furnace, at which time the ferric hydroxide in the residue is converted largely to ferric oxide, which is insoluble, while the zinc is unaffected and may be dissolved. (1,167,700-1, Jan. 11, 1916.)

Removal of Cadmium from Zinc Ores.—In view of the greater value of spelter free from cadmium, for certain commercial purposes, it is desirable to free cadmium-bearing zinc ores from this impurity before smelting them for their zinc content. Mr. GILBERT RIGG, of Palmerton, Pa., proposes to accomplish this by heating the ore to a temperature of from 700 deg. to 850 deg. C. in an atmosphere of a reducing gas, such

as producer gas. The process may be performed in an inclined rotary cylindrical kiln, heated internally by the combustion of the producer gas. The ore enters at the upper end and discharges at the lower. Provision is made for regulating the supply of gas and air, so that when the temperature of the furnace tends to decrease, the supply of air may be increased to restore the higher temperature. In fact it may be found desirable to operate the process with alternately high and low temperatures within the range indicated.

According to a patented modification of the process, the ore may be supported on a suitable grate, either stationary or traveling, within a furnace structure, wherein provision is made for a down-draft through the mass. In such case the fuel would be on top of the layer of ore, and as the heat penetrated downward the cadmium would be volatilized and drawn off in the gases. Instead of placing solid fuel on top of the ore, an ignited mixture of air and producer gas could be drawn downward through the bed and the temperature be alternately increased and decreased within the indicated limits until the cadmium was removed. (1,161,885-6, Nov. 30, 1915.)

Aluminium

Production of Aluminium from Clay and Other Aluminium Silicates.—Fig. 2 illustrates the flow-sheet of a process for obtaining aluminium from its silicate combination, the method being patented by GRENVILLE MELLEN of East Orange, N. J. The clay or kaolin is fused with sodium sulphate and sulphuric acid, or with its equivalent of sodium bisulphate, in proportions to form aluminium sulphate and free silica. After the reaction is completed the mass is cooled and dissolved in hot water or in a hot dilute solution of sodium sulphate containing a small quantity of aluminium salts from a prior extraction. The hot solution thus obtained

is filtered and the filtered concentrated if necessary. At this stage a concentrated solution of sodium fluoride is added, precipitating aluminium fluoride, which is separated by filtration. The filtrate containing sodium sulphate is concentrated to crystallize the contained salt which is again used in the process. The aluminium fluoride is fused with sodium chloride and electrolyzed, producing aluminium. By-products are pure silica, chlorine and sodium sulphate. The process is cyclic, as seen by the flow-sheet. (1,160,431, Nov. 16, 1915.)

Melting Aluminium.—A new process for melting aluminium or its alloys, having for its object the protection and preservation of the metal from oxidation and the production of sound castings, is patented by GRENVILLE MELLEN of East Orange, N. J. In carrying out the process the metal to be melted is placed in a crucible in an air-tight chamber. The air is then removed from the chamber and an inert gas admitted. After the metal is melted in this inert atmosphere, and while the metal is yet molten, the inert gas is removed from the chamber, thus producing a partial vacuum therein. Occluded gas is thus removed from the molten metal, and it is then ready for pouring, which should be done as quickly as possible. (1,160,430, Nov. 16, 1915.)

Vanadium, Uranium and Radium

A process for extracting vanadium, uranium and radium from ores is patented by RICHARD B. MOORE of the United States Bureau of Mines, Denver, Col. The process is that which has been used by the National Radium Institute, Denver, and which has been referred to in this journal, Dec. 15, 1915, page 965, and Jan. 1, 1916. It is also the subject of *Bulletin* No. 104, Bureau of Mines. Reference is here made to the patents to record the fact that they are dedicated to the public and can be used without payment of royalty. (1,165,692-3, Dec. 28, 1915.)

Electrolytic Processes

Electrolytic Cell for Treating Ores.—A revolving electrolytic diaphragm cell for the hydrometallurgy of ores is patented by LEWIS E. PORTER of Los Angeles, Cal. (one-half assigned to Hugh E. Stock of Casper, Wyo.). The cell consists of two concentric cylinders, the inner one forming the cathode and being made of metal and the outer one made of wood and provided on its inside surface with a number of plates which act as anodes. These plates are connected to an outside slip ring and the cathode is also connected to a slip ring. The cylinders are both on the same shaft and the outer cylinder is geared to a driving pinion for revolving the cell. Surrounding the inner cathode cylinder and close to it is placed another wooden cylinder constituting a diaphragm containing a number of small perforations and over this a filter cloth is placed. The action of the cell is as follows: The anode chamber, which is the outside annular space, is filled with ore through a suitable opening and electrolyte nearly saturated with metallic salt is forced in under pressure, filling any spaces not filled by the ore and being forced through the diaphragm and filter cloth into the cathode space between the diaphragm and inside cylinder. The ore in contact with the plates on the inside surface of the outer cylinder forms the anode and solution takes place, with metal subsequently depositing on the cathode. The cathode cylinder has horizontal wooden strips on its surface which divide the deposited metal into several strips, making it more easily removable. Suitable pipes are arranged for conducting away any gases formed in the anode or cathode chamber and the anode chamber pipe is provided with a safety blow-off valve, in case of too great a gas pressure developing.

FIG. 2—PRODUCTION OF ALUMINIUM FROM CLAY

The cell is stated to be applicable to the recovery of zinc from zinc ores containing considerable iron. (1,167,594, Jan. 11, 1916.)

Non-Metallic Cathode for Sodium Chloride Electrol-ysis.—A cathode for use in diaphragm cells which is intended to prevent the deposition of calcium or magnesium salts, found as impurities in salt solutions is patented by FRANK McDONALD of Roaring Springs, Pa. This cathode is made of graphite and a form of cell illustrating the use of this cathode is shown in Fig.

FIG. 3—CAUSTIC SODA-CHLORINE CELL

3. The tank or cell is cement-lined and the diaphragm is shown at 21 and the perforated graphite cathode at 20. The anode is shown at 16 and chlorine space inclosed above the anode space by slate cover 13 fastened to the cathode and diaphragm. Chlorine is conducted away through pipe 25 and caustic soda overflows from the outside cathode chamber through an outlet in the side not shown. The cathode and diaphragm are clamped to the raised cement projectory 11, and the cathodes are made porous by saw cuts in that portion which is below the solution. The diaphragm is of asbestos sheets. It is claimed that this cathode does away with the objectionable features of metallic cathodes in the use of which the internal resistance may rise owing to the deposition of non-conducting salts of calcium and magnesium existing as impurities in the salt solution, which would also clog the perforations of the cathode. (1,167,705, Jan. 11, 1916.)

Bismuth

Method of Purifying Bismuth.—A series of treatments forming a process for the production of pure bismuth is patented by WALTER C. SMITH of Chrome, N. J. (assigned to U. S. Metals Refining Co.) In the treatment four separate operations are performed as follows (not necessarily in the order given): 1. Sulphur is added to the molten impure bismuth metal while agitating and the temperature lowered to 515 to 520 deg. Fahr. By this treatment all of the copper and the greater portion of the tellurium, silver, arsenic, antimony, selenium and zinc, some of the tin and a fair portion of the lead are removed. The impurities form a matte which floats on top and may be removed. 2. Caustic soda is added to the molten metal and agitation commenced by steam. The caustic removes the tellurium, selenium, sulphur, arsenic, antimony, tin and zinc, forming sodium compounds which float on the surface. Silver and gold will be unaffected. 3. Zinc is added to the molten metal while agitating and the temperature lowered to about 550 deg. Fahr. This further

reduces the amount of silver present and removes all the gold. The remaining lead and practically all the remaining silver and any gold remaining are removed by crystallization. The steps may be modified or rearranged to suit conditions. (1,166,721, Jan. 4, 1916.)

Alloys

Electric-Resistor Material.—An alloy of nickel, copper and chromium to be used for electrical resistors is patented by MATTHEW A. HUNTER of Troy, N. Y. The alloy is stated to combine high resistivity with low temperature coefficient of resistance. The proportion of nickel used is large, relative to the copper and chromium and an alloy which has been found to give good results consists of the following: 85 parts nickel to 15 parts copper, with 20 parts chromium to 100 parts of nickel and copper. This alloy has a resistivity of 113 microhms per centimeter cubed at 20 deg. C., and at that temperature has a temperature coefficient of resistance of 0.000078 ohms per deg. C. per ohm. The copper increases the resistivity up to a certain point, and the chromium effects a reduction in the temperature coefficient of resistance. (1,168,074, Jan. 11, 1916.)

Copper Alloy.—An alloy consisting of copper, aluminium, antimony, iron and silicon is patented by WILLIAM C. PEASE of Marietta, Ohio. In making this alloy aluminium is first heated in a crucible, and while it is melting a piece of clay about the size of an egg per pound of aluminium is added. When this mass has thoroughly melted iron pyrite is added and stirred well. This is then poured off and broken into small pieces. One ounce of this mixture is added to 1 lb. of molten copper. The proportion of aluminium to iron pyrite is usually 16:2, although this may be varied. For further hardening the copper, antimony may be added. An average analysis of this alloy would be: copper, 88.4; aluminium, 6.6; antimony, 1.26; iron, 1.96; silicon, 1.60. It is claimed that the alloy may be molded, machined or forged. (1,168,962, Jan. 18, 1916.)

Electroplating

Continuous Electroplating Apparatus for Magnetic Material.—A continuous plating apparatus, designed primarily for electrogalvanizing pipes, rods, or other long, slender magnetic metal articles, is patented by NEWTON W. BUCH of New Castle, Pa. (assigned to Safety Armorite Conduit Co. of Pittsburgh, Pa.). A cross-section of this apparatus is shown in Fig. 4. The

FIG. 4—ELECTROPLATING APPARATUS

tank 2 may be made of any suitable width to suit the work to be done. The electrolyte 3 fills the tank as shown and anode members 4 are arranged toward the bottom of the tank. An endless chain having protruding pieces 13 fastened to it revolving on sprockets as shown passes through the solution. Below this endless chain or belt and in the solution is cathode member 10, which is turned up at the ends in order to facilitate introduction and delivery of the material to be plated. The cathode members, one of which is placed parallel to the one shown on the other side of the tank, form pole pieces for electromagnetic coils shown at 11, 12, 13

are cross-bars for supporting the cathodes and magnetic coils. The material to be plated is introduced at 14, is passed through the solution by the moving chain while being attracted to the cathode on account of its magnetic force. The material is delivered at 16 by the protruding members of the traveling belt. (1,168,281, Jan. 18, 1916.)

Electroplating Apparatus for Plating Pipes.—An apparatus for plating pipes and other magnetic material is patented by NEWTON W. BUCH of New Castle, Pa. (assigned to Safety Armored Conduit Co. of Pittsburgh, Pa.). This apparatus consists of a large cell having stationary anode plates and cathode racks or lifting frames consisting of a number of magnetic coils, suitably spaced on parallel bars and forming a coherent unit which may be picked up by a crane or other lifting device. The articles to be plated are placed in a rack, the magnetic lifting frame is placed on them by the crane and the current turned on in the magnetizing coils. The articles to be plated are thus raised up and conveyed to the cell or tank where they are lowered into place and disengaged from the crane. The magnets still hold on to the articles while they are being plated, and when finished they are again removed and replaced in their former rack by releasing the current in the magnet coils. The advantages claimed are that rapid and efficient work can be done and in large quantities at a time, and the articles can be plated all over, as no mechanical holder covers up any space. (1,168,280, Jan. 18, 1916.)

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver

Effect of Heat in Cyaniding Gold Ores.—The literature on this subject is scant and the data too general. In order to make a more careful investigation of the subject, Mr. E. A. WRIGHT has performed several series of experiments which he has recorded in *Bulletin* 135, Inst. Min. & Met. The first tests were made on a silicious gold ore containing about 7 per cent pyrites, and 4 oz. gold and 5 oz. silver per long ton. This ore was ground to pass a 60-mesh screen. It was agitated in duplicate quantities in hot and cold cyanide solution for definite periods. In the same manner a basic ore containing limonite and about half the gold and silver as the first ore. The ore was ground to pass 120-mesh. The results obtained from these ores indicated that agitation in a hot solution was of very doubtful benefit. In the first case the hot solution showed a better extraction than the cold for the first hour, but after that the hot solution was at a decided disadvantage. In the second case similar results were obtained, the hot solution giving better extraction for the first hour, but only equaling that of the cold solution at the end of four hours. In both cases, however, the consumption of cyanide was higher in hot solutions. In explanation of the results the author cites the fact that the solubility of gold in cyanide solution increases up to a certain temperature, beyond which there is a decrease. Further, the solubility of minerals like pyrite, in cyanide solution, increases with the rise in temperature, and probably the increased solubility of base minerals counterbalances the solubility of the gold, resulting in a greater loss of cyanide and a consequent decrease in gold dissolution.

Further experiments were made with heated air for agitation, using air at a temperature of about 350 deg. C. The results of these tests showed that while the hot air accelerated the rate of extraction, it did not give

as high a total extraction as under cold conditions. The acceleration noted is probably due to the increased activity of the oxygen, an idea which is apparently confirmed by experiments with hydrogen peroxide added to cold solution to supply oxygen in an active form. Other oxidizing agents, such as potassium bichromate and permanganate, were tested, with decidedly deleterious action.

The author concludes:

1. The effect of heating cyanide solutions is of very doubtful benefit; the extraction may be increased for a short period, but this is more than compensated by the increased cyanide consumption and the subsequent decrease in the rate of dissolution of gold.

2. Oxidizing agents (H_2O_2 excepted) are apparently of no value and may even exercise a deleterious effect on the extraction.

3. The addition of oxygen in a more active form, either as hydrogen peroxide or by means of heated air, increases the solvent activity of cyanide solutions in a very pronounced manner.

Copper

The Role of Sulphur in Pyritic Smelting.—In the course of his address as president of the Australasian Institute of Mining Engineers, Mr. Robert C. Sticht made the following remarks relative to the fuel value of sulphur in smelting at Mount Lyell. The complete address appears in the Institute *Proceedings*, No. 19, 1915:

"On its downward course the 'pyrrhotite' suffers a further desulphurization in the preparatory zone, in the hot current of neutral gases, under the influence of increasing temperature. It progressively loses more and more of its sulphur, until the particular combination of iron and sulphur, which finally reaches the focus, is even lower in sulphur contents than the monosulphide, FeS. Its composition naturally greatly varies, but for practical purposes it may be regarded as a solution of a little metallic iron in the monosulphide. Empirical formulae, like $4FeS$, Fe , and $3FeS$, Fe , are commonly indicated as representative of this residual sulphide when the working of the furnace is investigated by calculation.

"I do not, however, regard this high desulphurization as an advantage, but rather as a defect of our work—not on account of the possible liberation or precipitation of metallic iron in quantity, and the formation of 'sows' (a phenomenon which has never been observed at Mount Lyell), but because the particular sulphur and iron compound which thus reaches the focus is the one that does all the work there, and, under the circumstances, the shortage of even the small amount of sulphur involved is a drawback. It has not yet been possible to regulate the composition of the sulphide that burns in the focus, and it is possible that, if we could currently burn a composition more like FeS there, the small amount of coke which it is still necessary to use to furnish up the general furnace heat might be curtailed, or altogether avoided. The point seems rather fine, and the endeavor savors of splitting hairs, but it is certainly inaccurate to take it for granted, as is usually done, that it is FeS that burns in the focus, when it is actually a less energetic compound.

"From the foregoing it will be obvious that the sulphur in the original pyrites does not contribute very vitally to the heat developed in the pyrite furnace, notwithstanding its great quantity. The Mount Lyell pyrites now commonly has about 46 per cent of sulphur, and the North Lyell ore has 7.5 per cent. The ordinary furnace mixture of the two has about 30 per cent S.

Yet, of the original total S in the FeS, treated (*i. e.*, not counting the sulphur protecting the copper in its passage through the furnace), only 36-38 per cent actually is burnt in the focus as a fuel. A bare 2 per cent of the total goes into the matte, and from 55-60 per cent of the original S in the FeS, distills out of the furnace as sulphur vapor, without combustion anywhere, except in the shaft above the column, where it comes into contact with the atmosphere. The temperature at the throat is high enough to ignite it. These figures indicate the loss of a very considerable portion of the total inherent fuel value of pyrites.

"Unfortunately, there is no hope of realizing the calorific value of the sulphur thus escaping from the depths of the furnace, for the volatility of the vapor cannot be restrained, and the preferential affinity of the oxygen in the blast for the iron also discriminates against the combustion of the metalloid. Of the metal, iron, the furnace oxidizes quite regularly 95 per cent of the total contents in the ores. By contrast this represents a very valuable utilization of a constituent which is present in smaller quantity, and also has a lower calorific value, than the sulphur, for it saves the situation.

"There is, similarly, no prospect of utilizing any portion of the loose (*i. e.*, volatile) atom of sulphur out of the pyrites, which at once sublimates off at the throat. The suppression of all these eliminations would only be possible if the tension of the furnace atmosphere could be sufficiently increased to counteract the vapor tension of the subliming sulphur. This, however, is beyond the reach of our pressures, and impracticable in our apparatus.

"Were it feasible to burn the original FeS, in its entirety to the same degree as the Fe alone is now burnt, then the cokeless smelting would be accomplished. But it would have to be done in an apparatus differing very considerably from our present blast-furnace (or converter), and it is not easy to forecast the constructional lines of a closed, high-pressure structure, which it would have to show. It would have to embody all the accessibility of the throat for feeding and barring which the blast-furnace presents, together with a sealed tunnel-head, and at the same time be as simple to handle as our blast-furnaces now are. On the other hand, the mere raising of the blast-pressure in the existing furnaces will not lead to the combustion of noticeably more of the sulphur. Unless the ore column is simultaneously increased, a very heavy blast will only cause a waste of wind, by escape from the top, and the formation of a low-grade matte, owing to the lack of preparation of the descending masses in consequence of the rising of the focus. Some of the escaping sulphur may be burnt in such a case, but this will be above the stockline. Such back pressure as can be arranged for in the present furnace construction by means of tight charging-doors, etc., is insufficient to keep down the sulphur to any extent, and inadequate to force it to remain fixed until it gets to the focus in greater proportion.

"Something was hoped for in this general connection from the increase in height of the Mount Lyell furnaces. The column used to be 10-12 ft., and may now be carried up to 18 ft. No palpable effect has so far resulted from our efforts to cut down the coke and burn proportionally more of the sulphur. It must, however, be explained that just about the time the column was raised the percentage of Fe and S in the Mount Lyell pyrites began to decrease, while the Zn and Pb increased, and this change of composition has since become permanent. It has had an unavoidable deleterious effect on the heat developed by the charge alone, and, instead of being able to lower the coke, we have been obliged to raise it.

We are satisfied, however, that, with the former lower column, we would be obliged to use still more coke, for the same blast volume."

Crushing and Grinding

The Dumb-Bell Tube Mill.—In the *South African Mining Journal*, Nov. 13, 1915, Mr. G. A. ROBERTSON describes a new type of tube mill. Instead of using pebbles as grinders it contains a roller of dumb-bell shape. The mill tested was 3 ft. 6 in. long and 2 ft. 9 in. in diameter. The roller has its weight concentrated at the two ends, and each end has a concave face which fits two convex faces in the shell of the mill. As motion is imparted to the mill the roller revolves, and when ore is fed it becomes ground between the faces described. Both ends of the mill are the same, and it can be fed and discharged from both ends simultaneously. The dumb-bell mill is equipped with centrifugal classifiers fitted into the trunnions at each end. These classifiers revolve with the mill, and all particles of sand which drop into the pockets of the classifier are returned for further grinding. The following is a record of two tests made at the May Consolidated, using a sand feed of +0.0249 in.:

Mesh	Intake, Per Cent	Discharge, Per Cent	Mesh	Intake, Per Cent	Discharge, Per Cent
+ 30	3.5	—	+ 30	7.3	—
+ 60	29.5	0.5	+ 60	33.3	12.3
+ 90	19.2	22.9	+ 90	16.8	28.4
+ 200	12.5	22.8	+ 200	10.9	14.7
-200	35.5	55.8	-200	31.7	44.6
	100	100		100	100

Moisture, 92.3 per cent.
Duty per 24 hours, 5.2 ton.

Moisture, 90.4 per cent.
Duty per 24 hours, 6.5 ton.

The following figures show the mill's performance when fed at both ends and discharging at both ends. The feed passed a screen of 0.03-in. aperture:

Test	Screen	Per Cent		Moisture in Feed Sample, Per Cent	Duty Per 24 Hours, Tons
		Inlet	Outlet		
(1)	+ 60	31.4	11.1	75	16.5
	+ 90	16.5	24.1		
	- 90	52.1	64.8		
(2)	+ 60	24.7	15.6	Full battery water.	25
	+ 90	16.7	22.0		
	- 90	58.6	62.4		
(3)	+ 60	42.1	30.2	60	13.5
	+ 90	21.5	27.0		
	- 90	36.4	42.8		
(4)	+ 60	42.8	16.9	75	14.5
	+ 90	18.7	33.4		
	+ 200	12.2	16.7		
	-200	26.3	33.0		

In order to determine the performance of the mill with coarse feed, it was fed with material $\frac{1}{2}$ in. + 0.03 in. with the following results:

	Inlet	Outlet
+ 30	67.5	15.5
+ 60	18.5	40.5
+ 90	5	15.5
-90	9.0	28.5

Duty 7 tons per 24 hours.

It is estimated that 4 hp. will drive this 3-ft. 6-in. by 2-ft. 9-in. mill at 40 r.p.m. The capital expenditure is small and the wear is confined to the convex and concave faces of the shell and roller. The water line is practically a horizontal plane. Grinding is done both by impact and compression. The designer believes that the size of feed can be increased as the weight of roller increases.

The Mojave Tungsten Company, recently formed, is preparing to operate two developed, four partially developed, and several undeveloped claims in San Bernardino County, California. A modern concentrating mill will also be erected which may be used for custom purposes as well as for the company's own use. Several well known men are identified with the new company.

High Temperature Insulation

A Paper Read Before The Chicago Section of the American Society of Mechanical Engineers on January 14, 1916

BY P. A. BOECK

The problems of conservation of heat and prevention of thermal losses have been the subject of considerable investigation and research in certain industries, more especially in the application of cold-storage installations for low temperatures, and of steam lines and electric furnaces in high-temperature work. It has not been until recently, however, that this subject as applied to general industrial purposes, has received the attention of designers and engineers that its importance deserves.

Heat flow is a rather difficult factor to measure under the working conditions of an industrial furnace. It was not until the comparatively recent introduction into certain operations of the heat balance sheet, with a systematic attempt to account for the discrepancies in the totals, that the various causes of heat losses and the reasons for their existence were brought to light. Moreover, such rapid advancement and radical changes in the design of equipment, especially in metallurgical lines, have occurred that practice has apparently out-distanced the theory of design. In the modern tendency toward greatly increased size of units, effort has seemingly been made to utilize the heat of fuel gases without proper attention having been paid to conserving heat energy and confining it strictly to the points of maximum activity.

The work of several of the Government Bureaus, notably that of Bureau of Mines and Bureau of Standards, and the systematic investigation of the thermal properties of structural materials by a number of the technical societies are forming the basis for more intelligent and consistent work in the economically important subject of the prevention of fuel waste. We would refer to the recent excellent paper of L. B. McMillan¹ before this society. Here the point is made that it is not alone the efficiency of the insulator nor its initial cost, but a factor consisting of both of these items, together with the factor of durability or permanence, which form the ultimate criterion of the most effective insulator for any specific purpose.

FIG. 1 — TYPICAL WALL CONSTRUCTION WITH SILOCEL BRICK LAID IN WALL

FIG. 2 — TYPICAL WALL CONSTRUCTION WITH SILOCEL POWDER IN HOLLOW WALL

It should be unnecessary in this practical and utilitarian age to call attention to the need of preventing heat losses, but the consistent and intelligent application of insulation to high temperatures has brought out other advantages in addition to the saving in fuel. The most important of these advantages from an industrial point of view, is that of increasing the furnace capacity, it not being uncommon to add as much as 10 to 15 per cent to the furnace capacity without increasing the size of the equipment, the fuel consumption and overhead expense.

This is more evident when dealing with higher temperatures, considering that no matter how much fuel is consumed to produce a given product, the results are not obtained until the temperature attained is high enough to bring about the reaction. Any increase in the temperature and heat capacity of the equipment above that necessary to get results, produces an increase in output equivalent to many times the actual temperature difference.

The insulation of hot-blast stoves, for instance, is being advocated for the heat saved. This is a large and important factor which has been frequently brought out, but it is of minor importance when compared with the advantages of increased tonnage produced. Therefore, when the reference is made in this discussion to heat saving and increased capacity, we have in mind the effect of adding increased energy at the point of maximum effectiveness without additional fuel.

ADVANTAGES OF INSULATION

In any high-temperature apparatus if the heat can be prevented from being dissipated from the outside of the furnace, the temperature of the furnace is made more uniform and the zone of the reaction and consequently the capacity, are manifestly increased without additional fuel consumption. Furthermore, overheating at the source of heat in the effort to bring as much of the furnace as is possible into the zone of reaction, is materially reduced by preventing the loss through the furnace walls. This has the ultimate effect of lowering the temperature at the source of heat, greatly increasing the life of the refractories and the capacity of the furnace.

It is evident also, that in furnaces which are surrounded by metal casings, deterioration and damage caused by overheating may be many times as great as

FIG. 3—INSULATION OF BOILER SETTING BY MEANS OF SILOCEL BRICK AND POWDER

the cost of installing the proper insulation. The advantages gained by the protection of workmen from unhealthy and unsanitary conditions, incident to their laboring under over-heated conditions, are also apparent.

In general then, the question of insulation does not concern itself so much with the saving in fuel, which, of course, is an important item, as with the *general effect produced by confining the heat generated to points of maximum effectiveness*. The higher the cost of fuel, the more necessary it is to look closely to the preventable losses to gain an economically operated furnace.

HEAT FLOW

Inasmuch as the amount of heat conducted by a body is one of the principal sources of loss in high-temperature equipment which we have under consideration, it will be of interest to inquire into this in order that we may control the flow of heat by this method as far as possible. Heat is a form of energy consisting of molecular vibration of a periodic character, and subject to the general laws of wave motion. It can be reflected, refracted and dispersed by creating the proper conditions. In other words, by the proper mechanical manipulation we can increase or decrease, within certain limits, the amount or rate of heat flow. One of the most common ways of doing this is by introducing alternate layers of materials having different heat-transmitting values, thus breaking up or changing the wave length. The introduction of air cells or voids within the body is a most effective method of accomplishing the reduction of the conductivity. In fact, the apparent density of a body (which indicates the proportion of voids present) may be taken as an approximate criterion of its heat conducting capacity, i.e., the body is made more opaque to the propagation of heat vibration. This, however, is more apparent where the size of the voids are very small and the number great. Large voids have the effect of propagating heat by convection and radiation as will be seen later.

Heat is transferred from one place to another by three different methods, conduction, radiation and convection:

Conduction.—Conduction is the action taking place in the transfer of heat in which the heat energy is passed along from a particle at a higher temperature to a lower one by virtue of their contact. While this method of heat transfer applies to the three states of matter, it is only of magnitude in solids.

Radiation.—By Radiation heat is transferred from

FIG. 4 — TYPICAL WALL CONSTRUCTION SHOWING SILOCEL POWDER SUPPORTED BY METAL LATH, CEMENT FINISH

FIG. 5 — TYPICAL WALL CONSTRUCTION WITH SILOCEL POWDER SUPPORTED BY METAL CASING

one body to another without any material agency by wave motion; this applies only to the gaseous state of matter.

Convection.—Convection is that process of heat transfer in which some portion of the body whose temperature is raised, moves to another place in the medium where the temperature is lower, thus tending to raise the temperature of the medium. This method of heat transfer is therefore limited to liquids and gases.

STEAM BOILER

This is illustrated by the well known example of a steam boiler.² The heat generated by the fuel burning in the firebox is imparted to the dry surface of the boiler plate by radiation from the hot fuel bed, furnace walls and luminous flames, and secondly from the moving gaseous products of combustion by convection. From the dry surface it travels through the soot, metal and scale to the wet surface purely by conduction and is in turn transmitted into the boiler water mainly by convection.

The energy in the form of heat which eventually finds its way into the water in the boiler is, of course, subsequently available in other forms. That portion, however, which is transferred to the walls of the furnace setting by any of the three methods mentioned, is conducted through the setting and lost by radiation or convection from the outer surface of the setting, if means are not provided to prevent. It is the heat lost in this manner and methods for its prevention that will be especially considered in this discussion.

The selection of a boiler setting to illustrate the various methods for heat propagation was taken as that most familiar to general practice, but the selection is, unfortunately for the illustration, one in which the heat losses through the settings are comparatively low.

RATE OF HEAT FLOW

The rate of transfer of heat under various conditions, by both conduction and radiation, shows the relative importance of these two methods in influencing heat losses.³ The amount of heat conducted through a unit area from one part of the body to another is proportional to the difference in temperature of the two parts; directly proportional to the thermal conductivity of the body through which the heat passes and inversely proportional to the distance between the two parts of the body. In other words, the conduction of heat through a solid body from one place to another is a direct function of the conductivity of the body and the difference in temperature of the two planes, and an indirect function of their distance apart.⁴ This is identical with Ohm's law for transfer of electrical energy.

RADIATION

The heat transferred from one body to another by radiation is proportional to the difference of the fourth powers of the absolute temperatures of the two bodies. While this is strictly true only of the ideal "black-bodies," the variation is so small that for all practical purposes, this relation holds good in ordinary procedure.⁵

HOLLOW-WALL CONSTRUCTION

This relation indicates why a hollow-wall space is an effective insulator in low-temperature work, such as re-

²Kreislinger, Henry, and Ray, Walter T.: The Transmission of Heat into Steam Boilers, Bulletin No. 18, U. S. Bureau of Mines (1912).

³Convection and Radiation of Heat, Irving Langmuir, Transactions Am. Electrochem. Society, Vol. 23, p. 299 (1913); METALL. & CHEM. ENG'G, Vol. 11, p. 278 (May, 1913).

⁴Ray, Walter T., and Kreislinger, Henry: The Flow of Heat Through Furnace Walls, Bulletin No. 8, U. S. Bureau of Mines (1912).

⁵Gurney, Harold P.: Heat Radiation, Journal of Ind. and Eng. Chemistry, Vol. III, No. 11, p. 807, Nov., 1911.

frigeration, etc., whereas in high-temperature operations the loss of heat by radiation through a hollow-wall space is so great that its insulating effect is less than if this wall space were filled with material of rather high thermal conductivity. This has been brought out by Ray and Kreisinger who demonstrate that the hollow-wall space type of wall construction is much less effective as a means for preventing the loss of heat than a solid wall of any ordinary construction material of equal thickness. This is especially true if the air space in the hollow wall is near the furnace side and becomes highly heated. This is entirely contradictory to the general belief that, since air is a poor conductor of heat, air spaces built into the walls of a furnace will greatly reduce heat loss by radiation. While the heat does travel very slowly through the air by conduction, it leaps over the air space readily by radiation, because the quantity of heat which passes across the hollow space is a function of the fourth power of the absolute temperatures of the surfaces inclosing it, which loss is enormously increased by rise in temperature.

FURNACE WALLS

In general, in high-temperature furnace construction, there are two separate and distinct factors, which must be considered to produce an effective wall.

The first of these is to provide a material having the ability to resist the action of high temperatures, sufficient mechanical strength, and, possibly, the property of resisting corrosive slags, gases, etc., without spalling or being eroded.

Secondly, to prevent the excessive loss of heat due to conduction from the interior of the furnace to the outside where it is lost.

It is rare that a good refractory material is an insulator; usually it is necessary to augment or back up the refractory with some material having a much lower heat-conducting capacity.

REQUIREMENTS OF INSULATORS

The requirements of the insulating backing for the more refractory lining are rather severe. An ideal material would have the following properties: It should have an extremely high insulating value, and be sufficiently refractory so that no fusing or excessive shrinkage would take place in that portion which is in direct contact with the highly heated refractory wall. It should not be decomposed or be changed greatly in volume at the temperature, and it should, furthermore, be of light weight, unaffected by moisture, of convenient form, readily applied by unskilled labor, and low in cost. It should be of such composition as not to react upon or attack either the refractory material or the metal shell of the container, even in the presence of moisture; i. e., it should contain no free acid radicals, and should not be broken or caused to settle by vibration or heat. It should not have high expansion and it should be sufficiently elastic to take up strains between the lining and the shell produced by temperature changes.

While this is a rather formidable array of requirements, there are products upon the market which fulfill practically all of them. Such materials as are being commonly applied to steam-temperature insulation, of which magnesia and asbestos are best known, are, of course, eliminated from consideration in the great majority of cases mentioned here on account of decomposition, shrinkage and settling. The lack of more extended practice in high-temperature insulation must be attributed to the fact that effective high-temperature non-conductors have not been generally available.

AMOUNT OF INSULATION

When the kind of refractory material that is best suited to the surface has been determined, the next

most important item is the thickness of the walls and the nature of the insulating material most suitable, and it is necessary to determine the degree of insulation which will produce the most effective results.

Hering has pointed out that, in order to effect a perfect insulation, the furnace should be surrounded with an insulating material that would maintain the same temperature at any point as that of any adjacent point of the lining.⁶

In attempting to obtain perfect insulation, it is entirely possible to over-insulate, causing a serious damage to the refractories in the high-temperature zones of the furnace. To maintain the inner walls, it may be necessary to permit a considerable flow of heat through the wall, with a corresponding decrease in the temperature of the refractories at the heated point, in order to prevent their destruction.

It would be manifestly impracticable to insulate the roof of an electric steel furnace or open-hearth furnace, for instance, with a heavy layer of insulating material, because the cost of the refractory lining which would be destroyed would be considerably greater than the cost of the heat which would otherwise be lost.⁷

However, the issue in some instances may be met by other practical methods such as increasing the working capacity of the unit in order to make use of the additional heat available, rather than to let this valuable heat at the critical period escape to save the refractory lining. In calcining celite, the product which we will consider further in this paper, the temperatures are controlled entirely by the working load imposed on them

without allowing the oil burners to ever fall below their lightest working capacity and highest heat. To produce celite calcined to 2500 deg. F., an average kiln has a daily capacity of about 20 tons. When celite is wanted which has been calcined at 2000 deg., the kiln is pushed

FIG. 6 — HOT-BLAST STOVE INSULATED WITH SILICOCEL POWDER AND BRICK

FIG. 7—HIGH-TEMPERATURE FLUE INSULATION

to approximately 30 tons capacity and for a product treated to even less heat, the capacity is increased as high as 40 tons, the heat being the same in all cases.

In electric-furnace practice, where extremely high temperatures are encountered and where effective insulation is necessary because of the relatively high cost of current, the question of insulation, or rather over-insulation, has been given more attention than in other lines. F. T. Snyder⁸ has presented a detailed study of the nature and amount of insulation which is permissible under various conditions and presents many valuable data which might with advantage be applied to other industries.

DESCRIPTION OF CELITE

The requirements of an ideal insulator have been outlined, and in order to show the various methods of application which have been worked out, it will be well to select the insulator which apparently most nearly meets the requirements and use this as an example of methods of construction. In the applications shown, an attempt was made to cover as wide a field of use as possible, to show the scope of possible applications.

The mineral known as celite, on account of its extremely cellular nature, is a mineral of a highly siliceous composition and of very light weight, which occurs on the Pacific Coast⁹ in an exceptionally pure state. It is composed of numerous hollow cells, and weighs in its natural rock-form, air dried, from 25 to 30 lb. per cubic foot. When this material is ground properly, it weighs but 8 lb. to the cubic foot, and has a thermal insulating power of about 9 to 12 times the insulating power of ordinary firebrick. In other words, a 1-in. layer of this material is the equivalent in insulating value of from 9 to 12 in. of firebrick. Being almost pure silica,

⁸F. T. Snyder: *The Flow of Heat Through Furnace Walls*, Transactions of the American Electro-Chemical Society, vol. xviii, p. 235 (1910).

⁹Deposits worked by the Kieselguhr Company of America, New York, Chicago, San Francisco and Los Angeles. See the article by the author in *Metallurgical and Chemical Engineering*, vol. xii, p. 109; Feb., 1914.

its melting point is high, 2930 deg. Fahr. (1610 deg. C.), as reported by the Bureau of Standards, and it can be subjected to high temperatures without fear of alteration.

⁹It has been found advisable, however, not to use celite as a refractory at extremely high temperatures without some direct protection. This is readily accomplished by using it as a backing material for more refractory and highly conducting bodies. Owing to its remarkable non-conducting properties, the accumulation of heat on its face is so great due to the fact that the surface is not cooled by conduction, that a "flash" of flame or gases might easily exceed the melting point of silica and cause failure. If it is protected, however, only modified and uniform temperatures are encountered, which are maintained without damage.

It is possible further to prepare bricks and blocks of various sizes and shapes by sawing the natural material by means of gang saws. Standard 9-in. straight silocel brick made from natural celite weigh from 1½ to 2 lb. each and are equivalent in insulating value to many times their thickness of ordinary firebrick. In crushing strength these bricks withstand over 400 lb. per square inch, and are sufficiently strong to stand transportation and handling.

The high insulating value of silocel bricks can be shown by applying the heat of a blast lamp or torch upon their surface for hours, the unheated surface remaining cool enough to allow handling with ease. Powdered silocel can be tested in the same way by packing it into a shallow paper box of convenient size.

The cost of these insulating bricks is but little more than that of firebrick and that of the powder about one-third as much, so that the first cost of insulation is comparatively low. In fact, instances are on record where the entire cost of insulation has been saved in fuel in the first few months of operation, leaving the gain in equipment efficiency and increased output or capacity as a clear profit.

TYPICAL WALL INSULATION

Because of the variation in forms in which silocel products are supplied—that of brick, blocks of various shapes, in powdered form and as a plastic cement—this material is adaptable to almost any form of thermal insulation, as will be shown in the following typical examples:

GENERAL TYPES

In general, there are four forms of construction for high temperature insulation which can be adapted to almost any character of equipment.

Fig. 1 indicates the usual method of using silocel brick interlaid between a course of firebrick and red brick for the prevention of heat leakage through walls. This form of construction is largely used in boiler settings, bakers' ovens, reverberatory furnace walls and roofs, etc., and is generally applicable where a strong, solid non-conducting wall is desired. Metal bonds can, of course, be used if desired, and the insulating brick built up in a uniform course.

Fig. 2 indicates one of the methods of construction of an insulating wall in which an otherwise hollow space is filled with insulating powder. From 2 to 4 in. are usually sufficient. The powder is packed slightly to a density of approximately 12 lb. to the cubic foot, at which point it attains its maximum insulating value and is not subjected to settling or contraction due to either vibration or heat. Where this form of construction has been in severe service in high-temperature furnaces for a period of years, no contraction or settling has taken place.

FIG. 8—GAS GENERATOR SET INSULATED BY MEANS OF POWDERED SILOCEL

Fig. 3 illustrates the insulation of a boiler setting by means of silicel powder in hollow wall (left hand of diagram) and by means of silicel insulating brick (right hand and top of diagram).

Figs. 4 and 5 indicate the methods of insulating brick walls which are already in place. This form of insulation can be applied to old construction as well as new. In this method expanded metal lath is erected on an angle iron at the required distance from the outer wall and coated on the outside with one or more coats of Portland cement plaster, to which a small amount of silicel powder, approximately 20 per cent by volume, has been added to give greater plasticity and ease of working and to increase the heat-resisting properties of the cement. Silicel powder is packed to a density of 12 to 15 lb. per cubic foot between the brick wall and the expanded metal lath. This form of construction is relatively inexpensive and allows of as much insulation as is required, and furthermore gives an absolutely permanent surface of excellent appearance, which can be applied to almost any character of equipment.

INSULATION OF HOT-BLAST STOVES

Hot-blast stoves (Fig. 6) and mains (Fig. 7) serving a blast furnace give an interesting application of high-temperature insulation, a number of these having been insulated in the Pittsburgh and Cleveland districts with excellent results. The detailed figures relating to the increased capacity and the thermal data are being compiled and will form the subject of another paper. At the present time, complete figures are not available.

Both insulating celite brick and celite powder have been used for this purpose with apparent equal beneficial effect.

The advantages derived from the effective insulation of stoves and high-temperature flues have been pointed out by Maccoun, Johnson, Mathesius, Wysor and others, it being estimated that preventable heat losses from surface radiation varies from 8 to as much as 20 per cent.

Hot-blast stoves provide an excellent example of the requirements of an insulation for high-temperature work, not so much because of the high temperature to which they are subjected, but more especially because of the size, expansion and contraction of lining and shell, settling, shrinkage, elasticity and corrosion of the insulator and protection of the shell itself, the constant change in temperature and other factors.

In a 20 x 100-ft. stove, for instance, the column of brick in the lining may expand through heat as much as 5 or 6 in. in height from cold to maximum heat.

Therefore, the insulator may be considered at all times being subjected to a certain amount of stress and friction requiring an elastic medium which will take up these continued strains without injury or danger of being crushed which would result as is the case of granular slag in constant settling, the accumulation of fine material causing occasional bulging of the shell at the base of the stove on account of its inelastic nature. Two principal requirements of the insulator are, then, elasticity with still sufficient strength to give the proper support to the brickwork and shell, and, secondly, the proper amount of cohesion or high internal coefficient of friction and light weight as to overcome any tendency toward settling under the movement or vibration of the stove.

52-IN. MAGNET LIFTING SCRAP CAST-IRON COLUMN WEIGHING ABOUT 8 TONS

Lifting Magnets of Large Capacity

The lifting magnet has been adapted for the handling of materials in all branches of the iron and steel industry and has exerted a great influence in reducing the cost of handling many materials. Magnets designed for large lifting capacity in handling raw material have been placed on the market by the Cutler-Hammer Clutch Co., Milwaukee. These magnets are known as "High Duty" magnets and are designed especially for handling raw material. Recent improvements have increased the lifting capacity from 20 per cent for some sizes up to 60 per cent for others.

They are made in various sizes ranging from 18 in. to 62 in., the approximate lifting capacity of the 62-in. magnet being 4000 to 4500 lb., while in certain cases where a good surface is afforded the magnet will lift as high as 60,000 lb. Under adverse conditions the lifting capacity may drop to 2000 lb. For the 62-in. magnet a current of 72 amp. at 220 volts is required.

The frame or body of the magnet is made of a special grade of dynamo steel. The coils in the very small magnets may be made of wire, but for the larger magnets the highest space efficiency is obtained by constructing the coil of alternate turns of copper strap and fireproof insulating ribbon. The spool is of steel and forms a part of the inner pole. An absolutely tight

joint between spool and magnet case is obtained, thus eliminating all dead air space and facilitating rapid radiation of heat. It is necessary to design the magnet so that the heat of the coil may be quickly and easily conducted to the outside of the body from which it is radiated. This is effected by removing dead air spaces.

Another feature of the magnets is their waterproof construction. This is accomplished by first fully assembling the magnet, and when all parts are in their proper position, it is subjected to a baking process which is continued until all traces of moisture in the interior of the magnet have been eliminated. Air is next exhausted from the casing and a hot liquid filler is forced in under pressure, which presently hardens. One of these magnets was successfully operated 70 ft. below surface in the Mississippi River.

The magnets handle heavy castings, scrap, pig, and a great variety of other material.

Simplifying the Ore-Crushing Process

Simplification in all departments of ore treatment is noticeable in modern design and construction of machinery and plant. In the field of crushing and grinding we observe the simple ball and pebble mills for fine grinding, while for intermediate or secondary crushing there is a tendency away from the use of the small jaw or gyratory crushers or large rolls. These latter machines lose capacity rapidly as the required fineness of their product is increased, and they are readily choked by overfeeding. An efficient substitute for these machines is found in the Symons disk crusher, made by Chalmers & Williams, Chicago Heights, Ill., who present the following data from an investigation by Robert S. Lewis of Salt Lake City, Utah.

In the field of intermediate or secondary crushing, meaning the further reduction of the product of coarse breakers—a product from 3 in. to 6 in. in size—the common practice has been to use smaller jaw or gyratory crushers or large rolls. The tendency toward simplification is well illustrated in the late type of Symons disk crusher, which is particularly suited to this work of secondary crushing. Its freedom from heavy vibration, few and long-lived wearing parts, true crushing action, uniformity of product which contains very little oversize, and low first cost are bringing this machine into wide favor with mill men.

The crushing members are two dish-shaped disks of manganese steel placed with their hollow sides facing each other. These disks rotate in the same direction and at the same speed. They are supported at an angle to each other, so that there is a wider opening between the edges of the disks at one part of their circumference than at the opposite part. The material to be crushed is fed into the space between the disks through a central feed opening in one of them. Centrifugal force then throws the material into the space where the disks are widest apart, and on being carried around it is crushed as the disks come closer together. The action is a true crushing one and not a combination of crushing and grinding. Particles sufficiently fine are thrown out between the disks, while the larger particles are again subjected to crushing. The disks can be adjusted to compensate for the wear, and thus a uniform product can be maintained.

Sizes and capacities of these disk crushers are given in Table I.

Cost for repairs and renewals ranges from 0.2 cent to 0.6 cent per ton of ore crushed. In one case a set of disks crushed 130,000 tons of hard rock and gravel from 6 in. to 1 in. In another case, crushing ore, the record for two different sets of disks was 155,385 and 200,812 tons, at costs of \$0.0014 and \$0.00109 per ton, respec-

Size of crusher...	18 in.	24 in.	36 in.	48 in.
Size feed opening	1.5 in.	2.5 in.	3.5 in.	6.4 in.
Minimum exit opening and tons per hour for best results	5-8	1/2" 12-15	3/4" 25-30	1" 45-60
Minimum capacity, tons per hour, when crushing to size given	1/2" 8-10 3/4" 10-12 1" 12-15	1/2" 18-20 3/4" 20-25 1 1/2" 25-30	1" 30-45 1 1/2" 45-60 2" 50-60	1 1/2" 60-80 2" 80-100 2 1/2" 100-120
Horsepower required	12-18	18-25	30-40	50-65

tively, for disks. These records were made on 48-in. crushers, handling 45 tons per hour, crushing from 3 in. to 7/8 in. and requiring 35 hp. each. The total cost of operation for a period of eleven months was \$0.01598 per ton crushed, including an extraordinary cost of \$0.00228 per ton due to steel getting into the crusher, leaving a normal cost of \$0.0137 per ton crushed.

Chain Vernier Analytical Balance

The recently developed Christian Becker chain balance which is featured by its extreme simplicity, is shown in the accompanying illustration. The balance has a chain fastened at one end to the right side of the moving beam of the balance and at the other end to a slide arranged with a vernier. As this slide is raised or lowered

CHAIN BALANCE

the pull on the beam is increased or decreased, thus creating a series of different weights read from a scale on which the slide moves.

The chain is of gold and the slide is operated by a thumb screw from the outside of the balance so that weighing can be done with the window closed. The saving in time effected by simply reading the vernier and the doing away of small weight transferring are also important factors. Troublesome riders and small weights up to 50 mg. are eliminated.

The balances are sensitive to 1/20 mg. They are sold by Eimer & Amend, New York City.

The Manufacture and Uses of Alloy Steels is the title of Bulletin No. 100, United States Bureau of Mines, a timely publication on the properties and methods of manufacture of materials that are coming into wide metallurgical use. The chemical composition and physical properties of different alloy steels are given, both for those that find extensive use and others that are less well known at the present time.

Micrometer Reading Device

A reading device for thermometers and burettes which comprises a mechanically adjusted micrometer reading feature in addition to the magnifying lenses is shown in the accompanying illustration. The optical equipment consists of a combination of lenses, and in addition there is an adjustable lens with a very fine hair line through its center and connected to a graduated micrometer screw in such a way that it may be moved across a certain space in either direction. This makes it possible to subdivide the space between any two graduations of a thermometer, burette, etc., in from two to twenty parts. A small electric-light bulb which comes in back of the thermometer, burette, etc., facilitates the readings. The device is very light, being made of aluminum throughout.

In order to compensate for the error due to parallax a line is made on the small electric-light bulb so that three lines are available, the one on the lens, the line to be read on the thermometer, and the line on the bulb.

MICROMETER READING DEVICE

If the lens is adjusted until these three coincide each time no errors will occur.

To give an example of using this device, say the mercury of a thermometer graduated in degrees registers somewhere between 97 and 98 deg. C. The scale on the head of the micrometer screw is turned to zero, the movable lens with its dividing line set parallel to the graduation mark at 98. By turning the head of the micrometer screw, the dividing line will move from 98 deg. to the next graduation at 97 deg. As soon as it is parallel with 97 deg., we stop turning the scale, which may now read 12. Now we turn back the micrometer screw till the dividing line is parallel with the mercury thread, which is somewhere between 97 and 98 deg. We read off once more the scale of the micrometer screw, which, say, is 8. As the total distance of the mercury from 97 was 12 minus 8, which equals 4, then the exact point of the mercury in the thermometer was $97 \frac{4}{12}$ or $97 \frac{1}{3}$, not $97 \frac{1}{2}$, as it would have appeared with an ordinary reading device.

This device is known as the Lenzman Micrometer Reading Device and is sold by the firm of Lenz & Nudmann, Inc., Pullman Building, New York.

The Standard Calorimeter Company, East Moline, Ill., has issued catalog B, describing the Parr coal calorimeter, gas calorimeters, sulphur photometer and total carbon apparatus.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Aqueous Bath Apparatus

(Continued)

568,258, Sept. 22, 1896, Victor Joseph Kuess, of Bordeaux, France.

Relates to a process of and apparatus for distilling fatty substances, and consists of a steam-jacketed retort, the exhaust steam from which passes through the condenser to aid in drawing out the vapors from the retort. The retort is further internally heated, and the contents thereof treated with steam from a manifold having a plurality of perforations, steam issuing therefrom passing through the material to be distilled. The retort is also supplied with an electric resistance heating coil for internal heating, and also with a pair of parallel horizontal electrodes, preferably of aluminum, by which the ascending steam and fatty vapors may be subjected to electrolysis.

573,355, Dec. 15, 1896, Marshall Pridham, of Philadelphia, Pa., assignor, by direct and mesne assignments, to the Electric Rectifying and Refining Company of Camden, N. J.

Relates to apparatus for purifying and decolorizing saccharine liquids, water, etc., from nitrogenous, organic, or mechanical impurities, and consists of a preferably long rectangular tank containing electrodes; the tank is filled with the liquid to be purified by an injector which also thoroughly mixes the liquid with ozone. The liquid is electrolyzed by passing a current from an aluminum or zinc anode supporting a quantity of active material, such as aluminum hydrate, or zinc oxide, the active material passing to a negative electrode. Before electrolysis, the tank is exhausted of air or other gases, which removes entrained gases from the liquor. During electrolysis, a stream of ozone is injected, the ozone oxidizing the impurities, which settle to the bottom and may be drawn off. The aluminum hydrate also collects impurities under the action of the current, and settles either on the cathode, or at the bottom of the tank. If the liquor is not sufficiently purified, it is then sprayed into a cylinder containing air under pressure, the sprayed liquid being treated with ozone while entering the cylinder, and the liquid being treated with ozone by a perforated manifold, one section of which rotates in the cylinder. The liquid may then be subjected to a secondary treatment, by first exhausting the air, then admitting ozone through the manifold.

574,038, Dec. 29, 1896, Richard J. Marks, of Hartford, Conn., assignor of one-half to William P. O'Toole, of same place.

Relates to a work-holder for articles to be electroplated, the holder consisting of a pair of hinged wood frames, the top and bottom of which are covered with wire netting. The bottom covering is divided into four insulated sections, separated by wood cleats, the sections are connected to the negative wire from alternate ends, so as to provide a more uniform distribution of current to the articles to be plated.

591,730, Oct. 12, 1897, Willy Bein, of Berlin, Germany.

Relates to a process of and apparatus for electrolyzing solutions. The apparatus consists of a cell divided by impervious vertical partitions into two, three, or four compartments, the partitions not completely

separating the compartments from each other, but leaving a continuous liquid connection between them. With the four compartment cell, the two outer partitions extend downward from the top about three-fourths the distance of the cell, the intermediate partition extending upward a like distance. Above the intermediate partition, a depending adjustable gate is provided to vary the area of the liquid connection or passage. The outer compartments are covered, and in the electrolyte are placed horizontal electrodes near the surface thereof. Gaseous products pass off through vents, while products heavier than the electrolyte, such as sodium hydroxide, sink, and may be drawn off periodically. The electrolyte forms a fluid diaphragm between the anode and cathode, and is placed in the inner compartments; it is replenished as often as necessary. A modification consists in supplying a slow stream of electrolyte to the anode compartment, and allowing slow streams of anolyte and catholyte to siphon off from the electrodes. The patent should be consulted for details.

605,835, June 21, 1898, Emile Andreoli and Gabriel Andreoli, of London, England.

Relates to the electrolytic production of amalgams, and describes a horizontal cell consisting of two outer anode compartments, and a central cathode compartment, separated by porous partitions, the floor of which is covered with mercury. In the outer compartments are solutions of salt, and a layer of water covers the mercury to the height of the salt solutions. When the mercury is sufficiently rich in sodium, it may be withdrawn, and used for amalgamated copper plates to be used in the recovery of gold, etc., by amalgamation in gold mining. The central compartment may contain a mass of inert material, such as a block of cement, to provide a narrow channel for mercury next to the porous diaphragm, and thereby economize in mercury.

621,907, March 28, 1899, Herbert H. Dow, of Midland, Mich.

Relates to an electrolytic cell in which a layer of solution similar to the electrolyte surrounds a closed cell, thereby preventing any leaks of gas, etc.; or the layer of liquid may only cover the top of the cell. The liquid above the cell also filters into the pores of the carbon electrodes which project through the top of the cell, and into the cell, thereby preventing creeping of salts, etc., through the carbons.

625,489, May 23, 1899, William Y. Buck, of Bristol, Conn.

Relates to a work holder for electroplating, and consists of a metallic bar having alternate equally and oppositely inclined holes for the reception of articles to be plated, such as unmounted table knives. The tangs are inserted in the holes, the blades projecting upward and outward at an angle of approximately 50 deg. apart. The bar is suitably suspended in the electrolyte. During deposition, the more concentrated layers of electrolyte are at the bottom of the tank, and ordinarily this would result in a heavy deposit upon the tangs of the knives; in practice, however, the tangs exert a shadowing action upon each other, resulting in a relatively weak deposit. Since the blades are widely separated, they do not exert a shadowing action upon each other, and receive a normal deposit.

637,313, Nov. 21, 1899, S. Wicks, of Cleveland, Ohio.

Relates to an apparatus for sharpening files, and consists of a lead-lined tank containing a suitable acid electrolyte. The tank contains a plurality of vertical pockets in its walls, having open tops and bottoms, and perforated shields therefore, to prevent accidental contact of the cathodes within said pockets, and the files, which are connected as anodes. The files are separately electrically connected to the anode wire by a switch, and

are adjustably suspended vertically in the electrolyte.

645,785, March 20, 1900, W. Y. Buck, Bristol, Conn.

Relates to holders for electroplating spoons, etc., and consists of a pair of wires, twisted together at intervals, and leaving a plurality of rectangular loops between the twisted sections. The twisted wires are now bent in the shape of a rectangle, having a length several times its width, and provided with a handle or bail by which it is to be suspended in the electrolyte and electrically connected to the negative wire. The spoons to be plated are inserted in the loops, with the inner sides of the bowls facing toward the center of the frame. With this arrangement, the bowls receive a heavy plating on the outside, and a thinner deposit on the inside.

645,786, March 20, 1900, W. Y. Buck, Bristol, Conn.

Relates to the art of electroplating, and covers the process of "shadowing" surfaces of articles to be electroplated, thereby effecting a thin deposit on the shadowed surfaces, while producing a thick deposit upon the exposed portions. This patent is for the process used with the holder described in patent No. 645,785.

647,960, April 24, 1900, George Weltten Gesner, of New York, N. Y., assignor to Harleston Corbett Gesner.

Relates to an electrolytic cell comprising a vessel and an anode and cathode of an alloy of iron and hydrogen, the hydrogen being present in such quantity as to prevent all oxidizing action, including that arising from chlorine. The patent refers to several other patents and applications covering the alloy and processes for its manufacture. Several methods are briefly referred to in this patent, one of which is to force hydrogen through the molten metal, and then to remove the alloy that has been formed from the unalloyed iron either by puddling and squeezing, or by grinding and sifting. The alloy may contain hydrogen in the proportion of eleven one-hundredths of 1 per cent and upward. A cell comprising an anode and a cathode of this alloy is adapted for the decomposition of saline solutions, and salts which contain an excess of chlorine. The alloy is said to be capable of resisting oxidation and corrosion from heat or chemical action arising from either atmospheric or more powerful influences.

649,614, May 15, 1900, Antoine Edouard Peyrusson, of Limoges, France.

Relates to an electrolytic cell for the decomposition of electrolytes, and consists of concentric electrodes, the inner one contained in a porous cup which is provided with a faucet at the bottom, the outer one surrounding the porous cup and contained in an outer cell also provided with a faucet at the bottom. Both electrodes are in the form of a helix, and both fit tightly against the walls of the porous cup, and the cell. Fluids to be electrolyzed are admitted from faucets above, and travel in helical paths between the convolutions of the helical electrodes, the spaces between the convolutions constituting electrolyte compartments of considerable length. The velocity of flow of electrolyte may be controlled by the faucets at the bottoms of the inner and outer cells.

675,662, June 4, 1901, Samuel Lowe, of Waterbury, Conn.

Relates to a rack to support articles to be electroplated, and consists of a central vertical rod provided with a hook at the upper end, and a plurality of horizontal arms secured thereto, and extending each side thereof, and upon which the articles to be plated are placed. The upper horizontal arm has its ends bent upwards, while the lower arm has its ends bent downwards. In order to prevent the articles to be plated from slipping off the arms, end-pieces are provided having openings to receive the extremities of the arms, the upper and lower arms being sprung into place, their bent ends securely holding the end-pieces.

Industrial Notes

The Hooker Electrochemical Company's new plant at Niagara Falls is now in rapid course of erection by the Samuel Austin & Son Company. Probably 700 men are on the job now; at night, from 150 to 200. The entire work is being handled on a "cost-plus" basis. There is an engineering force of over sixteen men on the job, in charge of Mr. H. F. Jacobi. There is also a complete accounting force under an auditor, so that Mr. Hooker has on his desk each day at 9 a. m. cost reports covering each unit of work for the previous day.

C. W. Leavitt & Co., New York, have been appointed exclusive American selling agents for the Carlton Iron Company, English manufacturers of ferromanganese.

A dyestuff plant will be erected by Messrs. Marden, Orth & Hastings on a plot of land comprising ten acres in the meadows near Jersey City.

The Oliver Quartz Co. has taken over the business of T. C. Oliver, Charlotte, N. C. The quartz sold by this company has been used in packing a great many of the acid towers in eastern chemical plants.

The Pacific Coast Steel Company recently closed contracts for extensive enlargements to its plant to provide for the manufacture of structural steel on a large scale.

Bavarian Porcelain.—Messrs. Lenz & Naumann, Inc., New York, announce that they still have a good stock on hand of imported Bauscher Bavarian porcelain which is said to equal the Royal Berlin in acid, alkali and heat-resisting qualities.

The American Steam Pump Co., Battle Creek, Mich., has recently received an order for all the pumps to be installed in the new Curtis Bay distillery of the Republic Distilling Co., Baltimore. The order includes pumps for fusel oil, alcohol, gasoline, fresh and salt water, etc.

The Peruvian Potash and Chemical Co., Philadelphia, Pa., recently incorporated, intend to develop potash deposits in Peru. These deposits are stated to have lain for centuries untouched, with only a 3-ft. overburden of soft sand and gravel. The deposits lie on the southern boundary line of Peru, and are ten miles inland from the sea. Shipments to the United States are contemplated about April 1.

The National Ox-Hydric Company of Chicago, Ill., will install commercial oxygen plants for the sale of oxygen and hydrogen in Chicago, Pittsburgh, New York, Boston, Minneapolis, St. Louis, Kansas City, Detroit, Philadelphia and Los Angeles. Machinery and equipment for these plants is all completed and considerable of it has been shipped. The company will use its own generating system.

Japanese Electrochemical Works.—The British vice-consul at Osaka reports that a company has been formed in Osaka with a capital of 350,000 yen (about \$178,500 at par) for the manufacture of caustic soda and bleach by the electrolysis of common salt. A factory is to be erected at Kyushu where hydroelectric power is fairly cheap. The machinery is to be Japanese. A monthly output of 300,000 lb. of caustic soda is spoken of.

The Snyder Electric Furnace Co. of Chicago, Ill., announces sales of electric steel furnaces during 1915 from their English office at Bradford, Yorkshire, England, to the following companies: The Daimler Co., Ltd., England; Thwaites Bros., England; Summerson & Sons, Ltd., England; National Steel Foundry Co., Ltd., Scotland. In addition, four large furnaces for special smelting work have been contracted for as well as a small furnace for carrying on initial experimental smelting work.

Magnetic Separator Pulley.—A recent circular of the Cutler-Hammer Clutch Co. of Milwaukee describes its magnetic separator pulley for use in paper and pulp mills, cement plants, gypsum plants, starch mills, foundries, steel plants, mines, glass factories, rubber plants and other industries. This magnetic pulley is designed to remove stray pieces of iron and steel and is of particular value where crushing or pulverizing machinery is used, as by removing the nuts, bolts, pick-heads, etc., it prevents injury to the crusher blades. In other industries it is used to remove small particles that detract from the purity or quality of the product. An example of the latter is the sugar refinery.

Chalmers & Williams, Inc., of Chicago Heights, Ill., have received an order from the New Cornelia Copper Co. at Ajo, Ariz., for twelve 48-in. Symons fine reduction disc crushers, which will be used in their plant to reduce 4000 tons from 4 in. to $\frac{1}{4}$ in. Orders were also recently received for similar machines from the Chile Exploration Co., Hollinger Gold Mines Co., and C. S. Christensen, Kristiania, Norway.

The Apollo Electric Steel Co. has been organized for the manufacture of electric furnace steel at Apollo, Pa. A site of 8½ acres has been secured and the contract let for suitable steel buildings. They will be of the most modern construction and will be equipped with every facility for the manufacture of high-grade steel. Two Snyder electric furnaces will be used, each having a capacity of 100 tons per day. The management of the company will be in the hands of the following men: Robert Lock, president, formerly with Allegheny Steel Co. and American Sheet & Tin Plate Co.; J. Arthur White, metallurgical engineer, formerly with American Sheet & Tin Plate Co.; W. E. Troutman, manager of Vandegrift plant of United Engineering & Foundry Co.; J. E. Gallagher, of Apollo, and Carl H. Booth, vice-president of the Snyder Electric Furnace Co., Chicago.

Standard Tables for Petroleum Oils.—Samples of petroleum oil have been collected from different parts of the country by the United States Bureau of Standards, and the specific gravity determined over a wide range of temperature. From the data obtained tables have been prepared for determining the true specific gravity and volume of oil at the standard temperature, when these quantities are measured at other temperatures. Tables have also been prepared for showing the relation between specific gravity, Baumé degrees, and pounds per gallon. The new tables will be especially useful in determining the quantity of oil in large shipments. Circular No. 57 of the Bureau of Standards presents the results of these experiments, and it may be obtained by interested persons from that Bureau.

Measuring Barium Compounds in Rubber Goods.—By means of tests made on compounds of known composition, prepared at the U. S. Bureau of Standards, a method has been devised which permits the quantitative determination of barium carbonate in the presence of either lead sulphate or barium sulphate, the two sulphates most commonly used in rubber goods. This is of help in determining the total sulphur when both barium carbonate and sulphate are used as fillers. These tests are described in Technologic paper No. 64, which may be obtained from the Bureau of Standards.

The Riche Adiabatic Calorimeter, sold by Messrs. Lenz & Naumann, Inc., of New York, and described in this journal September, 1914, page 606, is reported to find increasing application where accurate results are required, on account of the many interesting features which make it an accurate measuring instrument.

Personal

Mr. A. A. Cole is the nominee for president of the Canadian Mining Institute. He has been known for his work as mining engineer for the Temiskaming & Northern Ontario railroad, with particular reference to the mining and metallurgy of the Cobalt and Porcupine districts.

Mr. Herbert Coward, who for three years has been in charge of the Spiro Turbine Department of the Buffalo Forge Co., and for four years previous engaged in sales and engineering work in connection with air conditioning apparatus, has been appointed steam engineer of the Carrier Engineering Corporation and is now located at its main offices, 39 Cortlandt Street, New York.

Mr. A. M. Douglass, formerly chemist in charge of the laboratories of the Merrimac Chemical and the New England Manufacturing companies of Boston, Mass., is now engaged in the installation of the plant and process of the American Bromine Company, located at Midland, Mich.

Mr. W. B. Easton, chief engineer for Chalmers & Williams, is visiting Arizona mills in the interest of his company.

Mr. Justin H. Haynes and Mr. Edmund Leet, who have been in the Cripple Creek district for the past five months, have completed their experimental work on flotation for the Vindicator Consolidated Gold Mining Co.

Mr. Henry Howard, vice-president of the Merrimac Chemical Co., delivered an address on the "Necessity for an American Dyestuffs Industry to Aid Export Trade in Textiles" at the National Foreign Trade Convention at New Orleans on Jan. 27-29.

Mr. H. C. Humphrey, chief chemist of the Eastern Branch of the Corn Products Refining Company in New York, died of pneumonia after a short illness.

Mr. S. A. Ionides has returned to Denver from a professional trip through the Northwest.

Mr. B. T. Klein has been appointed Pacific district manager of the Bristol Company. This is a new branch office recently established at 727 Rialto Building, San Francisco. Mr. Klein was Chicago manager for the company for six years and had charge of the company's exhibit at the Panama Exposition.

Mr. E. W. Lawler has again become associated with the Hardinge Conical Mill Co. and is located at the New York office. New quarters have been leased by the company at 120 Broadway in the Equitable Building, and it is expected that they will be at the new address by Feb. 20.

Mr. H. S. Mulliken is manager for the mines and smelter of the Penoles company at Mapimi, Durango, Mexico.

Dr. Charles S. Palmer, formerly professor of chemistry at the University of Colorado and later president of the Colorado School of Mines, has accepted a fellowship in the Mellon Institute for Industrial Research at Pittsburgh.

Mr. W. J. Pentland, general manager for the Amajac Mines Co., Hostotipaquillo, Jalisco, Mexico, is still at Guadalupe. In the last communication received from him, dated Dec. 28, 1915, he states that it has been impossible to carry on any work at the mines.

Mr. Charles F. Rand was elected president of the United Engineering Society at the annual meeting, Jan. 27, Mr. Gano Dunn declining re-election.

Dr. L. D. Ricketts has gone to South America to inspect recent developments in copper mining and metallurgy.

Mr. Frank W. Steere, vice-president of the Steere Engineering Co., Detroit, Mich., was awarded the "Beal Gold Medal" for the best paper read at the annual

meeting in 1914 of the American Gas Institute. Mr. Steere's paper was entitled "An Electrical Process for Detarring Gas," and was published in our issue of December, 1914, Vol. XII, page 775.

Mr. W. G. Swart has transferred his office from Denver to Duluth, Minn., where he is engaged on investigations relating to the treatment of iron ores.

Mr. S. W. Traylor, president of the Traylor Engineering & Mfg. Co. of Allentown, Pa., has been chosen manager of the ordnance department of the Crucible Steel Company's plant at Harrison, N. J. The new position will not interfere with his old one.

Mr. Thomas F. Williams, formerly chief mechanical engineer of the Aeromarine Plane & Motor Co., of Avondale, N. J., and a specialist in carburization of fuels, has accepted the position of chief consultant of the Board of Engineering Research, Mechanical Applications, of the Powdered Coal Engineering & Equipment Company of Chicago and will direct the research work of that company in the carburization of comminuted fuel and the application of automatic mechanical regulation and controls thereof.

Mr. Louis A. Wright has severed his connection with the General Development Co. and has joined the staff of the American Metal Co. He has sailed for Chile, which will be the scene of his activities for the next two years.

Book Reviews

Inventions and Patents. By Philip E. Edelman. 288 pages. Price \$1.50, New York: D. Van Nostrand Company.

This book is intended to be a practical guide to the inexperienced inventor who has not had the opportunity to know of the numerous obstructions in the way of applying for and securing U. S. patents. The author devotes a few pages to the development of the patent system and then in considerable detail describes the methods to pursue in choosing an attorney, making applications, patent office practice, methods of protection, sale of patents and so on. An appendix gives a digest of important patent decisions and the various forms used in patent procedure and closes with a short bibliography of the general subject.

The author has carried out his intentions in a successful manner, his style is easy, the language simple and non-technical. The book is well printed in good type and deserves a place on the shelves of every manufacturer.

Autogenous Welding and Cutting. By Theodore Kautny, translated from the German by the author and James F. Whiteford. 157 pages. Price \$1.00, New York: McGraw-Hill Book Company, Inc.

This handbook of the art of welding is a recent résumé of the latest practice in Germany and is intended to go directly into the hands of the operator in the works. It describes the methods of obtaining the various gases used, their purification, containers, pressure, regulation, piping and fittings. The author then devotes some pages to a description of blowpipes of various kinds and exactly describes their methods of use. Various kinds of metal are then taken up and the user is told just how to make vessels and articles of any shape. Copious illustrations assist the unusually clear description of operations and it is hard to see how a workman with average intelligence can fail to improve his technique by an occasional reference to this book.

The author is to be congratulated on laying before the public in so practical a way what has been too often considered in the light of trade secrets. No one who contemplates adding a welding department to his equipment should proceed before he has well studied this book.

The Power Famine at Niagara Falls and National Industrial Preparedness

Elsewhere in this issue (on pages 239 and 259 respectively) full reports will be found of two unusually interesting meetings held last month by the two liveliest and most aggressive local sections of the American Electrochemical Society, the Niagara Falls section and the New York section. At Niagara, under the chairmanship of Mr. F. A. Lidbury, the subject of discussion was the power famine at Niagara which has been growing worse from year to year and is now most serious in its threatening consequences. At New York City, under the chairmanship of Dr. C. G. Fink, the discussion related to "electrochemical war supplies" with special reference to national preparedness. Strange it may seem but it is true that the subjects of the two meetings are intimately related to each other. The discussions at both meetings deserve the most careful attention of everyone. We can touch at this place only on a few salient points of many which were brought out.

The fundamental trouble with waterpower legislation in this country in the past has been that those responsible for it have been too exclusively obsessed with one-sided aesthetic scruples and with the fear of the ghost of a waterpower trust and have never risen to a full realization of what developed waterpower means or would mean to the consumer and to the whole life of the nation. It is not generally and not clearly enough realized that the price this country is paying continually for the preservation of the spectacle of Niagara Falls amounts to something like a million tons of coal a week. Using another unit for expressing the economic equivalence, Mr. F. J. Tone brings the matter even more strikingly home to the public: if the Niagara power was devoted to the production of nitrogen fertilizer it would produce sufficient nitrogen for 3,000,000 bushels of wheat a day. Let it be clearly understood that the failure to develop available waterpowers means a continuous irretrievable economic loss of startling dimensions. The only real loser is the nation.

Mr. Tone's nitrate example is particularly appropriate because for the industrial self-containedness and for the very independence of a nation a sufficient nitrate supply is a fundamental prerequisite in peace and in war, for fertilizers and for explosives. The fact is that in the past this country has relied wholly on nitrate importations from Chile. Mr. W. S. Landis is right in pointing out that Germany has been able in a single year to make itself independent of importations by rapidly developing electrochemical nitrate processes on a marvelous scale, and he is also right in saying that with respect to the production of cyanamid and subsequent transformation into ammonia and nitric acid "there are

no problems the solution of which is not now resident in the United States, and therefore we feel that this country is to-day in as good, if not in a better position to supply its own nitric acid for ammunition purposes than Germany was at the beginning of the war." But to state the facts in the case completely, it must be added that the only large American cyanamid plant is not in the United States, but on the Canadian side of Niagara, and that the cyanamid industry is one of those which were forced by the power famine on the United States side to go out of the country. When it comes to figure the cost of undeveloped power and the economic loss of the country, let the expatriation of industries of fundamental importance be not forgotten.

We cannot expect too much from our law makers, but we expect that something be done. Mr. Albert H. Hooker's proposal is excellent. Well over 1,000,000 hp. more could now be developed at Niagara and not a bit of injury would be done to the scenic grandeur of the cataract if a little engineering skill were used in placing the proper brakes and deflectors. Let this be done with the provision that for every 100,000 hp. newly developed, say, 10,000 hp. be devoted to the fixation of atmospheric nitrogen; the more varied the methods the better. In any sensible program of preparedness chemical preparedness and chemical self-containedness must be fundamental and nitrate production from the air must play a big part; the crux of the matter is more Niagara power. The American electrochemists may be safely relied upon to do the rest.

Metal Prices and Wages

The wage earner in the mining and metallurgical industries is sharing with the operator in the profits flowing from the increased prices of the base metals. The daily press cites numerous instances of wage increase and of sliding wage scales based on metal prices, particularly in the copper, zinc and steel industries. Lead has not yet shared in the general advance in as great measure as the other metals.

Utah mining and smelting companies generally have granted advances, the Utah Copper Co. alone being reported to have increased its pay-roll by about \$50,000 per month. Kansas and Oklahoma zinc smelters and Joplin mining companies also have granted substantial increases. Colorado and Eastern iron and steel workers have been recognized, and wherever unusual profits are being made the worker is sharing in some degree. Conditions are in marked contrast with those of August, 1914, when production was curtailed and workmen were offered employment on half time.

The attitude of the operators is wise as well as just. The workman is entitled to a share in the enhanced value of his product. This is no time to incur his enmity or ill will, for he is a factor that cannot be ignored. We like to believe that the operators recognize the justice of these wage increases, and that they are not merely placating the men through fear of dissension or strikes that would mean cessation of operations and consequent loss. And signs are not lacking that an intelligent view of coöperation is surely re-

placing the sentiment of antagonism that prevailed all too widely in the ranks of employer and employee only a few years ago. The millennium is not yet at hand, but we are in a fair way to avoid repetitions of the distressing state of affairs that recently prevailed in Arizona for four months, and which has been settled on an amicable basis. A point to be kept in mind by both sides is the necessity of being equally considerate and tolerant when prosperity is not as marked as it is to-day.

A Most Remarkable Steel Situation

If the situation now obtaining in the steel market had been portrayed a year ago the sketch would have been considered fantastically fanciful. The reality is difficult to grasp. It seems impossible. The future of a market is a resolution of the forces, but in this instance no resolution seems reasonable; it looks as though it would have to be in the fourth dimension!

The steel industry, the industry of making soft steel by the Bessemer or open-hearth process, is not very old. The art passed its semi-centennial several years ago, but it was not until about a quarter century ago that the manufacture of puddled iron in the United States ceased to increase. Thus the history of the steel market is not so long but that it can be scrutinized for possible parallels. None can be found. Soft steel became the dominant wrought ferrous product during a period of industrial depression, and at its close there was a "boom," prices skyrocketing in the latter half of 1899, but the boom was short lived, and the total turnover at high prices was small from a tonnage standpoint. The next upward movement, culminating in 1902, found finished steel products under such control, a control that proved quite temporary, that they advanced unduly with respect to material in its cruder stages. Since 1902 the steel market has attained three high points, in 1907, 1909 and 1912. Of these the highest was that of 1907. At the end of 1915 the average price of finished steel products was level with the high point of 1907, \$4 a ton above the high point of 1909 and \$6 a ton above the high point of 1912.

It seems to be a fair statement, therefore, that at the end of 1915 the steel market was on the verge of passing beyond bounds. The period 1905-6-7 represented the greatest period of sustained and heavy demand in the history of the steel industry, and to produce higher prices than then reached would certainly require altogether exceptional and extraordinary conditions. Since the first of this year the steel market has advanced an average of fully \$7 a ton, being by that length virtually out of bounds, and the going is still strong. The curve of prices is concave to the blue sky. In bars, plates and shapes, for instance, the nine advances that occurred in the first ten months of 1915 were of \$1 a ton each. Then came advances of \$2 a ton each, and the latest advance, made about Feb. 18, was \$5 a ton. It would be instructive if the formula for the graph could be written, dx being first of the order of \$1, then of the order of \$2 and then of the order of \$5.

The manner of doing business in steel is likewise

without precedent. Hitherto as prices advanced the steel mills would cover their customers farther and farther ahead, so that the advance in prices realized upon shipments would be quite gradual, and buyers would be well protected for the future. In this movement the mills began to curtail the making of contracts after prices had reached a moderate level, and of late they have been disposed to accept little but specific orders. The following of such a policy has tempted buyers to make up dummy specifications, which parade as specific orders, buyers knowing that the mill cannot ship for months and that opportunity will therefore be afforded to change the specification when the real wants are clearly seen. Thus the tonnage of so-called "specifications" on mill books is not as close an index as usual to what the mills will actually be called upon to deliver.

From the viewpoint from which the steel market has been regarded in the past the present situation would be impossible, and the future likewise impossible. One usually judges the future in human affairs by mapping out the possible courses of events and selecting the most probable, as the railway engineer selects the most feasible course for his proposed road. When he finds no possible course, however, he loses his job. There is no reasonable course for the steel market now to follow. Prices are already above the traditionally "safe" level, yet show a greater advancing tendency than ever. That might be held to suggest a break in the market in the near future, but a break seems to be as improbable as anything.

It is a question, however, whether there has been any really conclusive test in the past as to the ability or willingness of steel buyers to pay one price or another. To an extent the matter has hinged upon what the buyers have been able to obtain for their product, for it is rarely indeed that the ultimate consumer buys steel from a mill. As a rule steel markets have been made or broken not by the ability of the buyer to pay, but by what he expected of the future, whether prices were likely to advance or decline. His ability has not been seriously tested.

In any event, however, the "buyer of steel" is not a homogeneous quantity. One buys steel to make watch springs, another to build a bridge. There are all gradations. With sufficient detailed knowledge the buyers could be classified, the aggregation analyzed, and the groups arranged in the order in which high prices would curtail the expression, in actual orders, of their requirements or desires. If the desire to have steel represents neither more nor less than the quantity of steel that can be produced, and price exercises no deterrent influence, the production will be bought. If the desire exceeds the supply, the price can be a deterrent, as to various classes of steel, to the extent of this excess, and still leave purchases equal to the possible supply. If at any moment the deterrent is less than this excess, relief is found in price advances.

The extent to which high prices may be a deterrent to steel purchases may be overrated if the average experience of the past be taken as a guide, for the propor-

tions in which steel has been bought of late are quite different from the proportions of the past. There has been a much smaller proportion of structural material and a much larger proportion of steel for automobiles and most other classes of material. If all the steel now being shipped could be followed to its ultimate destination, where it is to perform its actual service, the value in the case of a great percentage would be found to be a large multiple of the price received by the mill, whether that price were a cent and a half a pound or three cents a pound. In ordinary times it does not follow that the price would not be an important consideration, the buyer perhaps concluding at times it would be better to wait. The times now, however, are so disorganized that the buyer has no idea what is coming. Some buyers would not buy now even at low prices; others may care nothing for price.

If little is known as to the prospective willingness of domestic buyers to pay high prices for a large tonnage of steel—for at present the high prices are being paid for but a small tonnage of the steel shipped, owing to the filling of old orders—still less is known as to the export demand. It is currently observed that prices bid for export steel are higher than the regular prices asked in the domestic market, but the mills have been so busy arranging their orders that they have negotiated on little of the export inquiry. In good times prior to the war the great iron and steel exporting countries, Germany, England, Belgium, France and the United States, have furnished about 10,000,000 tons a year to the non-producing countries. At the present time such exports are at a rate probably somewhat under 4,000,000 tons, a trifle more than one-half being furnished by England. Obviously there is room for a large increase in our export trade, as England can scarcely increase her exports, provided the price will be paid. Imagine a conical shaped vessel containing water, with an outlet at the bottom. How much water must escape to reduce the pressure one-half? No answer. Is the cone upright or inverted? Thus with the pressure for steel for export, which causes high bid prices. One does not know how much tonnage would be sold before the bid prices would be greatly reduced.

In all this confusion one thing seems reasonably certain. When the turn comes, whether it be relatively near at hand or far distant, steel prices will not drop with the dull disheartening apathy that has characterized such declines in the past. Wants that were not expressed when prices were higher will be found expressed in orders as values decline; the buying cannot come to a sudden standstill.

The common view in the steel trade has been that the heavy demand for steel will last during the war, and even the sharper advances in prices now occurring have not served to convince the majority that the break in steel prices is likely to come sooner. The observation, of course, presupposes that the war will not be continued until complete exhaustion overtakes the belligerents, for in that case their purchases of American products would have ceased, and with it a part at least of our general industrial prosperity would end.

Readers' Views and Comments

The Chemist on the Board

To the Editor of Metallurgical & Chemical Engineering:

SIR:—Chemists are just like other men, and when they grow rich they are likely to become vain and cocky. Not all of them by any means; some are of such exquisite mental balance and are so wholesome of disposition that the more wealth and power they achieve the better it is for everybody all around. And yet very few of us are proof against the danger that accompanies the accession of wealth, or against the need of a camel ride, or against the vain belief that, so mounted, we can easily make the grand tour through the needle's eye without so much as losing any skin or compressing our camel. We know that others would have trouble and we even have concern lest they fail, but it is not so with us. We have just the balance, just the quality of poise, of *savoir faire*, of grace and general sensibleness to make it especially desirable that we be rich. This is our great illusion.

We say this because we believe it to be true, and more especially to take the sting out of what we are about to say. Observe, please, chemists are like other men and other men are like chemists. If they grow rich they are likely to suffer in character and in modesty. As soon as anybody has made his pile he may need to be treated with caution lest he flare up and lose his head and strut about and grow angry and demand more reverence and respect and admiration and obedience than his qualities warrant. The longer the credit balance the shorter the temper as a rule, and its operation can only be overcome by a well-oiled and easy-running condition of that part of a man's internal equipment that functions as generosity. By this we mean the larger generosity whereby one understands not only what another thinks but how he feels, and has the sympathy to avoid giving unnecessary pain. This quality is one wholly separate and apart from executive ability and good business sense.

Now if you want a competent board of directors to guide the affairs of an industrial undertaking, you must select men of experience and achievement in affairs and such men are likely to be rich. If they are, there is the danger that at least some of them may be crippled by rich man's vanity. You may sit on a board with such a man for years and not know he is suffering from this malady, and again, under some unexpected provocation it may crop out at any time in the form of a broad, yellow streak, to your amazement and distress.

In any concern engaged in the production of goods by means of chemical processes, there should be a chemist on the board for advice and to avoid mistakes. This for the same reason that there is a lawyer, either duly elected or present as general counsel, in like manner to avoid mistakes. It was intimated in the last issue of this journal that business men and especially bankers do not know chemists as such, and that few of them know the difference between a good one and a bad one, or how to tell them apart. The bad chemist has the advantage over the good one with men of business because he can promise so much more. There should be chemists on the boards of many corporations that are now even boastful that they haven't a single "theorist" in their whole establishment, if they are to avoid unnecessary waste and keep out of trouble. To hear some directors talk it would almost seem as though they would discharge a man if he owned a slide rule. It has

been so firmly insisted upon of late, however, that there is something in this chemistry, after all, that the style may be set some day to have "a chemist" on the board of directors of a manufacturing corporation. American business men, like some of their frailer sisters, are disposed to take "The Easiest Way"; and the easiest way in this connection would be to send down to the works and tell young Brown or Jones or Robinson who may be testing materials in their cupboard of a laboratory somewhere under the stairs, to come up to the office and sit in.

Then suppose the most affluent, the most pompous, the vainest if not the richest director, the father-in-law of the secretary of The Sand & Stone Co., were to offer the following motion: "Resolved, that, prices being equal, this corporation shall purchase its rock from The Sand & Stone Co." The young chemist apologizes for speaking and says that Sand & Stone are agents for Blue Mountain rock and that this rock seemed to show traces of Dubium which he fears might give trouble in the works.

"Whatcha mean?" roars the affluent one to the pale B. S.

"Well—I—er—it doesn't seem to me that it works as well as the Earth & Rock Co.'s product that I believe comes from Green Mountain. I thought I found traces of Dubium there, and, you know, there might be a catalytic effect—"

"Cataclysmic Effect!" exclaims the affluent one. "Young man, is that what you think or what you guess?"

"Why, I'm not sure but I think—"

"That's what you think, is it? Well, sir, when you know something let's hear from you, but we don't care for any of your guesses. The Sand & Stone Co. are the largest dealers in this material in the world and if I tell them to send us rock without any of this here Dubium in it, they'll send it. I call for my motion, Mr. Chairman."

The motion is put and carried.

In one year's time the asset of the corporation's name as a trademark becomes a liability; they cannot persuade people that their product is not tainted. Even after they have seen the folly of their ways and given up the use of Blue Mountain rock and turn out a product better than ever before, their reputation is still bad.

"Better not buy of 'em," says one customer to a prospective one. "They tried to run off a lot of inferior material on me, but I made 'em take it back."

"One of their drummers was in not long ago and he said they had had a fault but had corrected it; they had some Dubium in their rock they make it of, but he says it's all right now."

"That's what they say! Jever know a concern that wasn't all right when they wanted to make a sale?"

"That's so. Better be on the safe side," says Mr. Prospective Customer, and he buys from the rival company.

Now suppose instead of electing the young chemist from the works, a consulting chemist of standing is selected, retained and added to the board to avoid mistakes at the start, which is the Grand Economy. Let us imagine the same corporation, same chairman and president, same pompous old party with a son-in-law with Sand & Stone, same general counsel and the same other members except that Dr. Noyadont of the Noyadont Laboratories sits in the place of young Brown, the

chemist at the works. Unlike Brown, Dr. Noyadont has not bought himself a house in the neighborhood of the factory and has not married on the prospects of the good-will of the very board of which he is a member. Dr. Noyadont likes his annual retainer, which may be more than Brown's salary, but he does not live on it. Then let us imagine the same proposal of the affluent Mr. Fatwad that the corporation procure its rock from Sand & Stone.

Dr. Noyadont speaks up: "Sorry, Mr. Fatwad, but I shall have to oppose that motion. I've examined the Blue Mountain rock that they handle and it is not good for our purpose."

"Why not?"

"Appears to be Dubium in it."

"But these people are the largest producers of rock in the world and do you mean to tell me——?"

"I mean to tell you not to use any Blue Mountain rock. It's the best there is for some purposes, but not for us."

Old Fatwad observes that Dr. Noyadont is neither afraid nor uncertain of his ground. But he likes to have his way and he proposes a committee of three including Dr. Noyadont to ascertain—

"No occasion for me to look into it any more," says Dr. Noyadont. "Go ahead and buy all the Blue Mountain rock you want to," he continues, "but with it comes my resignation from the Board and from the office of your consulting chemist. Mr. Fatwad expects your processes to move on all calm and serene in the presence of a catalytic agent that may start up all sorts of reactions that you don't want. I can't be sure of your product under those conditions. If some member of the board were to propose to break the laws of the state or the nation, your General Counsel here would advise you against it, and if you were to persist in it he would resign. Well, here you propose to break Nature's laws and expect to keep out of trouble after you've done it. I call for the question, Mr. Chairman, because it involves a matter about which we should not be in doubt for one minute. And I offer my resignation now to take effect as soon as the motion is carried."

Mr. Fatwad then withdraws his motion. He may see a light and again he may not, but the chances are that he will, because he is nobody's fool. But rich-man's vanity is one of the most difficult things to overcome. When it is quiescent it is invisible and harmless; when it is active it is hard to endure and highly dangerous. The only way to deal with it when it is active is to whack it on the head. No employee can do this without providing for himself first, a good, safe runway into the tall timber.

There should be a chemist on the board of every corporation that has to do with chemical processes. He should be a man of attainment, of distinction and of backbone.

ELLWOOD HENDRICK.

New York City.

Engineers Interested in Preparedness.—The Monday night lectures given at the Engineering Societies Building, 29 West Thirty-ninth Street, New York, on military subjects under the direction of Maj. Gen. Leonard Wood are attracting large audiences. On the first Monday night, Feb. 14, more than 2300 engineers tried to attend. It was necessary to turn between 500 and 1000 away, even after holding an overflow meeting for 500 in a separate hall, where the same lecture was given as in the big auditorium but by another army engineer. The speaker in the large auditorium was Capt. Thomas M. Robins, who spoke on the duties of engineers in war, and what engineers in civil life will be called upon to do.

The Power Famine at Niagara

Meeting of Niagara Falls Section of American Electrochemical Society

(From Our Special Correspondent)

The Niagara Falls section of the American Electrochemical Society discussed the power situation at Niagara Falls at its February meeting, held at the Assembly Room of the Niagara Electric Service Corporation on the evening of February 2. A large and representative body of Niagara Falls electrochemists was present, and the proceedings were marked by a definiteness of purpose and intensity of interest of quite unusual order.

The chairman, F. A. Lidbury, opened the meeting with an explanation of the reasons for which it had been called. He pointed out that those present had long foreseen that the governmental restriction of power development at Niagara must ultimately result in the present situation, in which the shortage of power was seriously hampering the electrochemical industries and through them the industries of the country at large. Individual members had done what they could from time to time to point this out publicly, but there had been no concerted effort. It was time for this condition to cease and for members to stand together and to do whatever was possible to bring about such changes as would relieve the situation.

What the section could do was the main matter for discussion. He thought himself that its usefulness would be largely educational. Firstly, they had to educate themselves as to the situation. This was the main object of the meeting. Very few knew, for instance, how much power was generated on this side of the Niagara border, and how much imported from Canada; how much of the total amount was used for electrochemical purposes, how much for other. Secondly, they had to educate the local community; there ought to be a better realization of the dependence of the city's growth and prosperity on a continually increasing power development; thirdly, he pointed out the growing influence of technical societies and advised the education among their own and related societies of members as to the national importance of the matter; and, fourthly, they had to attempt to educate the people at large, who were fully awake to the significance of the dye situation, but quite ignorant of the far greater importance of the electrochemical industries, because the matter had not been properly brought to their attention. He asked F. L. Lovelace of the Niagara Falls Power Company and J. L. Harper of the Hydraulic Power Company to explain the present situation to the meeting.

F. L. Lovelace gave an interesting historical sketch of the power development at Niagara and of legislative acts restricting it. He contended that the limits set by the Burton Act, which limits were at present being insisted upon by the government in spite of the fact that the Burton Act had expired and the treaty with Canada allowed 4400 cu. ft. sec. more, were unfair to the Niagara Falls Power Company and that it had been the intention of the treaty convention in extending these limits to correct an error in the Burton law so as to permit the operation to full capacity of the plant of the Niagara Falls Power Company. He concluded with an analysis of the Kline bill now before Congress and showed that the result of this bill would be not only to make operation more difficult and restricted, but to place the whole of the present developments in jeopardy.

If Mr. Lovelace's address was, perhaps naturally, rather a piece of special pleading on behalf of the

Niagara Falls Power Company, that of J. L. Harper, who followed, dealt in an extremely witty manner with the situation from the point of view of the Hydraulic Power Company, Mr. Harper ironically thanking that company for their efforts to secure the extension of diversion limits from the 15,600 ft. of the Burton Act to the 20,000 of the treaty. He sarcastically observed that the "growing influence of technical societies" might result in such control of meteorological conditions that ice troubles resulting in intermittent service might be avoided. He appeared to think that much influence might be exerted by associations of industries dependent upon electrochemical products—this, one presumes, on public opinion and legislation, not on ice. Two points from his remarks aroused general interest—first, his admission that "if the power companies had been together in anything beside their woes, conditions might have been very different;" secondly, his estimate that the total flow of the falls represented about 5,000,000 hp., and his contention that a suitable system of submerged weirs could so distribute the flow as to render 60 per cent available for power purposes and provide a grander spectacle than at present with the remaining 40 per cent, while at the same time diminishing the natural erosion at the peak of the horseshoe where the large volume of water is now running over without assisting the spectacle in the least, but resulting in the recession which tends to denude the remaining portions of the fall of water.

In answer to a question Mr. Harper said that the Niagara Falls Power Company generated 90,000 hp. and the Hydraulic Power Company 100,000 to 125,000. All the latter, except 15,000 hp., was employed in the electrochemical industries.

F. J. Tone, who followed, spoke on the subject of *Niagara Power and Industrial Self-Containedness*.

This concise statement would lose so much by summarizing that it is quoted in full:

If the year 1915 has shown us one thing more clearly than another, it is that a nation must be economically and industrially independent. Some of our economists have told us from time to time that a nation should not strive to be self-contained; that America should confine itself to the development of its most abundant resources, for example, those of agriculture, lumber, coal and the heavy manufacture of iron and steel, and that we should let Germany supply us with our potash, dyestuffs and fine chemicals, England with our ferromanganese and Chile with our nitrates.

The year 1915 has shown us to what economic distress such a policy leads. We have seen crude potash advance from \$35.00 to \$400.00 per ton—a point where its use as a fertilizer has practically ceased. We have seen England place an embargo on ferromanganese and the price advance from \$38.00 to \$125.00 per ton. Magnesia, the basic refractory of the steel manufacturer, has become almost unobtainable, and the same may be said of numberless commodities, including emery, barytes, carbolic acid, crucible graphite, platinum and dyestuffs.

I wish to point out a few ways in which the whole question is bound up in Niagara power, and to show the paralysis of industry that would follow if the electrochemical companies of Niagara Falls could not continue to meet the call that is being made on them. Few realize how many industries are directly dependent on chemistry. Still less has it been realized to what extent our great basic American industries depend on electrochemistry, and specifically on the electrochemical products of Niagara power.

I first wish to mention the steel industry. The manufacturers of steel, the greatest of all American industries, are to-day absolutely dependent upon Niagara power by reason of its requirements in ferro-alloys, such as ferrosilicon, silicon metal, ferrochrome and ferromanganese. In 1915 there was produced in this country about 28,000,000 tons of steel, 20,000,000 tons of which was basic open-hearth steel, and in 75 per cent of this there was used as the main deoxidizing agent high-grade ferrosilicon produced in the electric furnace by Niagara power. All ferrosilicon made by electric furnaces in America is now produced from Niagara power.

It is an absolutely essential element in 15,000,000 tons of steel.

The most striking example, however, of the intimate relationship between the metal working industries and Niagara power is that of high-speed steel. The essential alloys in the manufacture of high-speed steel are ferrochromium, ferrotungsten and ferromanganese. All of these are produced in Niagara, and they are also made elsewhere by the use as reducing agent of metallic aluminum, likewise a product of Niagara power. If the supply of high-speed tool steel were cut off there are hundreds of metalworking industries where the output would be reduced to 25 per cent of their present rate.

Ferrochrome is also the hardening element in armor plate and armor-piercing projectiles, and not a battleship is afloat but what has many tons of it in her armor; yet up to three years ago we were dependent on Europe for one-half of our supply.

In other special steels, such as silicon steel or electrical transformer steel, we also find an almost total dependence on the products of Niagara power.

The abrasive industry is one intimately connected with industrial life. Without adequate grinding materials the most important industries of the country, including the manufacture of automobiles, agricultural machinery, steel and malleable iron, marble, granite and all finished products of iron and steel, would be greatly handicapped and in cases their output would be reduced to a fraction of their present rate. The abrasive situation to-day is another striking illustration of the dependence of industry on Niagara power.

Abrasives are of two kinds; the natural abrasives, which are Turkish and Grecian emery, and the artificial abrasives, such as carborundum, alundum and aloxite. Ten years ago artificial abrasives represented 22 per cent of the total consumption. In the year 1914 they represented 55 per cent. Since the war, however, the mining of emery has almost ceased. Not a pound of Turkish emery is being shipped, and shipments from Greece are negligible.

There are four artificial abrasive plants operating with Niagara power, and they produce all the artificial abrasives used in this country. Their annual output is about 20,000 tons. If this supply were cut off a partial paralysis would follow throughout the metalworking industries.

As an example, take the automobile industry. One of the big western manufacturers plans during 1916 to put out 1000 cars per day. In the factories of that company grinding machines form about 25 per cent of the tool equipment. The crank shafts are roughed and finished with grinding wheels, the cylinders are bored with grinding wheels, balls and ball bearings cannot be produced without grinding wheels. It takes 500 wheels per month to grind forgings alone. If we could conceive that these works were forced to go back to the grindstone and were at the same time deprived of high-speed tool steel, aluminum, oxyacetylene welding and other products produced by Niagara power, it is not an exaggeration to say that their output would drop from 1000 to 100 cars per day, with the same plant equipment and the same number of workmen. The cost of the car would be multiplied by ten, which simply means that there would be no automobile industry.

Aluminum and calcium carbide, the largest of the electrochemical industries from the point of the power consumed and value of the products, were first made possible by Niagara power, and on these products, as well as other Niagara products, such as bleaching powder, alkali, chlorine, phosphorus, graphite, sodium and cyanides, depends a whole line of America's basic industries.

To-day nitrogen products are unquestionably the most important products in the field of chemistry. Without them modern warfare, as we know it, would be impossible, because they are an essential element in every explosive.

The success of Germany in making herself independent of Chilean nitrates in a single year is an industrial achievement of the highest order, but nitrates are not merely a war product. They are necessary in the life of an agricultural nation at all times and, as a matter of common foresight, the production of artificial nitrates should to-day be made an established industry in America. This does not mean that we should at once produce all the nitrates required, but partial development should be encouraged, which would enable the industry to be perfected in its chemical and technical organization so that it could meet any natural or political emergency. This at once calls for cheap electrical power in the center of good transportation facilities, and, in brief terms, it means that we must have Niagara power in large amounts and at low cost.

The only nitrogen fixation works operated by Niagara power is the American Cyanamid Company, and this pioneer industry was forced to go to the Canadian side to obtain

sufficient power. America has 25,000 horsepower devoted to nitrogen fixation and Europe over 300,000 horsepower. We are startled when we are told that for the spectacle of Niagara we are paying the price of a million tons of coal a week. I believe it is more startling to put this in terms of America's food supply. If Niagara was devoted to the production of nitrogen fertilizer it would produce sufficient nitrogen for 3,000,000 bushels of wheat per day.

In any program of industrial preparedness and self-containedness chemical preparedness and chemical self-containedness play a big part, and its crux is more Niagara power.

L. E. Saunders elicited from P. P. Barton of the Niagara Falls Power Company the statement that from 125,000 to 150,000 hp. was being transmitted into the United States from the power stations on the Canadian side at Niagara Falls. Mr. Saunders pointed out that this importation depended on permits revocable by the Canadian government, and indicated that the revocation of these permits was not so distant as people imagined. The generation of large quantities of additional power at Niagara on the American side, and rapidly, was the only way by which a frightful dislocation of American industry could be avoided.

H. R. Carveth stated that it was necessary, as development of power had been restricted by popular voice, and as popular opinion traveled as a pendulum swings, to take advantage of the return swing from the influence of the J. Horace MacFarland *Ladies' Home Journal* agitation. It was a question whether the return swing had already started or not.

NIAGARA FALLS POWER AS A NATIONAL DEFENSE NECESSITY

Albert H. Hooker spoke of the present campaign for national preparedness, and considered a much larger development of Niagara Falls power as a national defense necessity.

The largest industries of the country, steel, paper and chemicals, now find these electrochemical products vital raw materials without which they cannot operate. Many of these products so useful in times of peace are called for in vastly larger quantities in times of war. Not only the equipment, but the skilled electrochemists, mechanical engineers and operators are needed for the manufacture of these products. The provision of such skilled labor in these specialized industries in times of peace, as an emergency measure, is fully as important as compulsory military service and should be considered as a branch of the same broad plan. As regards the electrochemical industry such development could only take place where economic conditions were favorable for the economical production of power of the highest commercial value. For this industry, Niagara Falls occupied first rank and now holds first place as the world center of the industry, with the greatest force of active workers in this field anywhere in the world.

Even now some of our industries were compelled through lack of power to move to Norway and other fields, while unused water which could be consumed without injury went to waste and we start the training of a foreign army of electrochemical workers on foreign soil.

Germany's interest in the electrochemical industry and the fixation of nitrogen has been her salvation at this time, and we should consider her interest in the dye industry as a measure of preparedness. The same benzol, toluol, caustic soda, nitric acid, chlorine and sulphuric acid used in times of peace in the manufacture of dyes are used in times of war for the various nitro explosives; the same equipment is used and the same army of skilled chemists and workers familiar with the latest details of nitration processes are in constant training. Should we not consider the

training of this industrial army and the development of our water power and electrochemical industries as of particular importance now as a matter of preparedness in National Defense?

After some further discussion, on the motion of Mr. Saunders, the chairman appointed a committee of the Section to deal with the matter along the lines suggested in the discussion. The chairman appointed F. J. Tone (chairman), H. R. Carveth, I. R. Edmonds, F. A. J. FitzGerald, A. H. Hooker, H. W. Kellogg, W. S. Landis, F. A. Liddbury, C. H. Moritz, L. E. Saunders, W. A. Smith, A. T. Hinckley (secretary).

The Western Metallurgical Field

Potash from Kelp

The Hercules Powder Company has let a contract to Charles C. Moore & Company of over \$500,000 for the erection of a kelp plant in San Diego, Cal.

Swift & Company are also building a new potash plant at San Diego, having completed their experimental work in the plant which they leased for that purpose in San Diego.

Cooperation Between U. S. Bureau of Mines and Colorado School of Mines

On Jan. 29, 1916, a cooperative agreement was signed by Van H. Manning, director of the United States Bureau of Mines, and William B. Phillips, president of the Colorado School of Mines, which is expected to react to the benefit of both parties and to aid in the metallurgical development of the State. The present Denver office of the bureau is to be removed to Golden next June, and thereafter metallurgical research will be conducted under joint auspices. Under the terms of the agreement the school offers the bureau the use of the building known as Engineering Hall, which will be slightly remodeled to meet the bureau's needs.

This arrangement has been concluded with the object of avoiding duplication of work; to obtain an interchange of information; and to cooperate in the conduct of investigations having particular reference to the development and utilization of the mineral resources of Colorado and the West. The experimental mill and testing plant of the school will be available for this work as far as may be necessary, and in general the laboratory and library facilities will be at the disposal of the bureau.

Details of the work that will be undertaken and the exact method of cooperation have not yet been determined, and will be left to the discretion of the proper officials of the school and the bureau. It is recognized by all concerned that the success of the arrangement depends on active and genuine cooperation, and it is expected that harmonious relations will be established and that the industry will profit from the close contact of these two centers of metallurgical research.

Improved Industrial Relations in Colorado

The marked change that has come over the spirit of capital and labor in Colorado since the war-like conditions of 1914 is reflected in the *Industrial Bulletin* of the Colorado Fuel & Iron Co. This company is one of the largest employers of labor in Colorado, operating numerous coal mines and the Minnequa steel works at Pueblo. In former years there has been more or less disagreement between the company and its employees, culminating in actual warfare two years ago this spring. Echos of those conditions are still heard in the courts, where miners are being tried for their part in the destruction of life and property.

Apparently a new day has dawned, and employer and employee are going to understand each other better.

They are coming to a belated recognition of the rights of each, and of the necessity for cooperation for mutual good. It will be remembered that out of the strife of 1914 grew a proposal of the junior Rockefeller for industrial representation among employees and company officials, for the purpose of harmonizing differences of opinion. That plan is now being put into effect, and conferences have been held. The president of the company has appointed an "industrial representative" for mines and one for the steel works, their duties being indicated by their official titles.

In the January issue of the company's *Industrial Bulletin* we note an editorial on "Democracy in Industry," from which we quote a few lines that show the tenor of the new relations: "The growth of large corporations seems to demand some such step as a means of insuring justice to every employee. In large measure this plan brings all employees of the company into close relations with the officers, somewhat as was possible in the old days when the individual employer with a small group of employees took a personal interest in the welfare of each member of his business family. There are many honest critics who regard this as paternalism and as doomed to failure. But there is every evidence that C. F. & I employees believe that a real partnership of these two interests is possible—a partnership based on friendship, mutual interest and fair dealing. This company is squarely committed to democracy, as contrasted with paternalism, in all its relations with its employees."

Engineering Research Proposed for Columbia

In the annual report of Dean F. A. Goetze of Columbia University he discusses the proposition of establishing at Columbia an engineering research laboratory similar to those in Germany which he visited some time ago. The proposed scheme is pretentious and involves the expenditure of about \$500,000 for building and equipment, and an endowment of from two million to five million dollars. In comparing the relative cost and value of the proposed engineering research laboratory with that of the proposed building for applied science on the university site, Dean Goetze states that "with the same amount of money we could buy a site with railroad and water facilities within five minutes' walk of the university, erect on it a building twice the size, of a modern factory construction much better suited to our purposes, and have about \$150,000 left over for equipment." After speaking of the endowment he expresses the opinion that "no other university is so favorably situated by its environment, prestige and traditions to lead in this important field."

Conditions in Mexico

The recent massacre of members of an engineering party in Mexico has acted as a bar to the early resumption of work at some mines. The conditions which resulted in this sad incident have not been confined to any one part of the country, and bandits are active wherever they feel reasonably secure from molestation by agents of the *de facto* government. In a recent letter from an engineer now at Guadalajara, commenting on the fate of the engineers in Chihuahua, he says: "We walked into a trap like those poor devils did, but thanks to four of our men who learned of it in time and who caught the bandits in the rear just as they were about to attack us, we got away and back to Ixtlan, while the bandits scattered after losing one man. We got an escort and returned, but found none awaiting us that trip." Such conditions speak for themselves and show what prospect American engineers have in starting or continuing mining and milling operations in Mexico. It is more

than likely that such conditions will prevail for some time to come, and life and property will be in jeopardy. Sporadic outbreaks will occur, becoming less frequent as time goes on, with bandits pillaging and murdering, until the government becomes strong enough to insure peace. In the meantime American engineers apparently are without assurance of safety while remaining or traveling in Mexico.

Company Reports

The seventh annual report of Stratton's Independence, Ltd., contains a resume of operations for the seven years of the company's existence, and an interesting comparison of the results actually obtained with those anticipated by the original tests of the dump. For the year ended June 30, 1915, the mill treated 116,778 tons of ore, of which 74,849 tons came from the old dump and the balance from the mine. The average gold content was but 0.1468 oz. per ton. There was recovered in concentrates 37.31 per cent of the total, and in bullion 38.66 per cent, or a total of 75.97 per cent. The first-grade concentrate averaged 4.031 oz. gold per ton and the second-grade 1.61 oz. These products were sold to smelters. The following table gives a summary of milling cost:

Operation	Per Ton
Coarse crushing and sorting.....	\$0.199
Fine crushing, concentrating and treating concentrate.....	0.515
Cyaniding and special chemicals.....	0.478
Miscellaneous expense	0.171
Total milling cost.....	\$1.363
Mining dump ore.....	0.150
Total cost	\$1.513

Compared with the previous year the tonnage treated was less, the extraction lower and the cost higher.

Mr. Argall, consulting engineer, who originally recommended the construction of the mill and the treatment of dump ore, adds some figures to show how his estimates have been confirmed in practice. The estimated value of the dump ore, obtained through the expenditure of \$9,500 for sampling, was assumed to be \$3.60 per ton. Based on a 70 per cent extraction and an operating cost of \$1.52 per ton, Mr. Argall believed that a net profit of \$1 per ton could be made. A summary of six years' milling operations shows the treatment of 671,665 tons of ore containing an average of 0.1522 oz. gold per ton, yielding an average extraction of 74.57 per cent at a cost of \$1.5138 per ton. Thus it is seen that the average value of the ore was slightly lower than the estimate; the recovery was considerably higher and the cost slightly lower. If a monthly tonnage of 10,000 tons had been treated continuously the net profit of \$1 would have been fully realized.

Throughout its history to the date of sale to the Portland Gold Mining Co., Stratton's Independence mine produced ore of a gross value of \$23,621,728, yielding earnings amounting to \$8,116,778. The present company paid in dividends \$455,625 and had cash on hand, after selling the property for \$372,000, amounting to \$510,000. Having closed its business in the Cripple Creek district of Colorado, the company is now looking for a new property.

The report of Camp Bird, Ltd., for the period ended June 30, 1915, shows that both profit and tonnage for the year exceed the estimate of a year ago, and that there still remains in reserve a profit almost equal to the estimate of a year ago. Cost of both mining and milling are lower by 12 cents per ton each than they were during the previous year. The total cost of operation is lower by 98 cents per ton. The profit amounted to \$583,700, an increase of \$186,380 over the preceding year. The mills were in operation 357 days, and the saving was 96.03 per cent of the gold value and

94.31 per cent of the combined gold and silver value. Of the total recovery, amalgamation yielded 58.48 per cent; concentration, 36.59 per cent; cyanidation, 4.93 per cent. The recovery of metals per ton of ore averaged 1,333 oz. gold, 3.78 oz. silver, 1,048 per cent lead and 0.16 per cent copper. The value per ton of the recovered metals was \$29.47, as compared with \$26.19 last year. The amalgamation and concentration mill treated 32,313 dry tons of ore. The cyanide mill treated 20,655 tons of tailings from amalgamation and concentration. Dividends paid amounted to £100,476 (\$487,308).

The Santa Gertrudis Co., Ltd., states in its annual report for the period ended June 30, 1915, that operations at the property in Mexico have been practically continuous under the adverse conditions that have existed. Development work has continued, and the ore reserves are estimated at 1,287,000 dry tons, sufficient to last about three and a half years under normal conditions of production. The estimated metal content in the ore reserves is 81,086 oz. gold, and 16,217,296 oz. silver, 90 per cent of which is recoverable. The Guadalupe mill remained closed during the year, although 268 flasks, or 10.09 tons of quicksilver was recovered from the old patio. Work at the new mill has been far below capacity owing to the difficulty of obtaining supplies. The gross tonnage treated amounted to 211,669 dry tons of ore having a gross value of 26s. 2d. (\$6.28) per ton. The recovery in bullion amounted to 90.31 per cent of the gross value. The average daily tonnage treated was 580 dry tons, compared with full capacity of 1111 tons.

The Coniagas Mines, Ltd., in common with other producers of silver, suffered from the reduced demand and lower price of that metal in 1915, according to the annual report for the period ended Oct. 31, 1915. The concentrating mill at Cobalt, Ontario, ran 98.83 per cent of the possible time, milling 55,437 tons of ore, at the rate of 3.02 tons per stamp per 24 hours. The average silver content was 23 oz. per ton. High-grade silver concentrates amounted to 473.9 tons, containing 2175 oz. silver per ton. Low-grade slime, averaging 233 oz. silver per ton, amounted to 133 dry tons. Sand tailing contained 2.89 oz. silver, while slime tailing carried 6.36 oz. per ton. The average tailing carried 3.94 oz. The high-grade mine ore shipped amounted to 267 dry tons, containing an average of 3520 oz. silver per ton. Total shipments of silver for the year amounted to 2,002,053 oz. The cost of mining and concentrating was 13.618 cents per ounce of silver produced. The cost of shipping, smelting, refining and marketing was 3.252 cents per ounce. Dividends amounting to 21 per cent, or \$840,000, were paid. Silver reserves are estimated at over ten million ounces. An addition to the mill is under construction for the purpose of cyaniding about 6 tons per day of low-grade canvas table concentrates and decomposed slime or gouge from the mine. It is estimated that this plant will effect a saving of about \$100 per day.

The Consolidated Mining & Smelting Company of Canada, Ltd., made a net profit of \$795,411 during the year ended Sept. 30, 1915, after writing off \$192,479 for depreciation. Dividends amounting to 8 per cent, or \$464,398, were paid, leaving a balance of \$331,013. The total credit to profit and loss account is \$2,058,300. Important additions have been made at the smelter to provide for the production of refined zinc and copper. The manufacture of zinc is a new departure, but is expected to develop into an important feature of the company's operations. Copper matte, hitherto refined in the United States, is to be refined in Canada. Further improvements consisted in purchase of the right to use the Cottrell process of fume recovery for roasters and blast

furnaces; construction of an additional lead furnace; construction of a new lead sampling mill. The experimental electrolytic zinc plant was operated during the year, producing spelter of good grade at the rate of $\frac{1}{2}$ ton per day. A permanent plant of about 35 tons daily capacity is now under construction. Smelter production for the year amounted to 148,891 oz. gold, 2,230,500 oz. silver, 40,177,910 lb. lead, 5,306,184 lb. copper, all from 447,064 tons of ore and of a gross value of \$6,898,744.

The Iron and Steel Market

Steel prices have advanced during the past fortnight more rapidly than ever. On Feb. 15 steel pipe and line pipe, 12-in. and under, was advanced one point or about \$2 a ton, oil country goods being advanced \$2 to \$4 a ton, while wrought-iron pipe was likewise advanced \$2 a ton. At about the same time wire products were advanced \$2 a ton. On Feb. 17 the Carnegie Steel Company advanced bars, plates, shapes and hoops \$5 a ton, previous advances having generally been \$1 or \$2 a ton, and other mills immediately followed in this action. The price of \$3.75 on tin plate, which had been gradually disappearing, became altogether nominal, yielding to an actual market of \$4 to \$4.25 for 100-lb. cokes.

The attitude of the mills in advancing prices so sharply, when they were already at the highest level in a dozen years or more, is not clearly disclosed. As a rule when the mills advance prices it is because they have booked all the business they care to book at a certain level but are prepared to book a considerable additional tonnage at a higher figure. In this instance they are still reserved about selling. Either they expect practically fabulous prices to be paid for large tonnages of steel in future or they feel that a break in prices would not be the formidable event it usually is.

The average price of finished steel products, including bars, plates, shapes, pipe, wire, sheets and tin plate, weighted approximately according to their tonnage importance, has advanced from 1.42c. in December, 1914, when the lowest level in fifteen years obtained, to 2.07c. at the close of 1915, equal to the average level of 1907, and to 2.42c. at the present time, representing a total advance of \$20 per net ton, two-thirds of the advance having occurred during 1915 and one-third during the first two months of this year.

There is a divergence in the extent to which the mills are definitely sold up and the extent to which they are committed to customers. The Steel Corporation's statement of unfilled obligations at the end of February, to be made public March 10, will probably show it sold up, on an average, to the latter part of September. It is not certain that all the tonnage will actually be taken by customers, while on the other hand there are promises to take care of regular customers, representing important additional obligations which preclude the acceptance of much tonnage from new buyers. Many steel buyers appear to be quite fearful that the regular sources of supply will be unable to furnish them all the steel needed during the second half of the year.

Pig-iron production is at the rate of about 39,000,000 gross tons a year, production of ingots and castings at the rate of about 41,000,000 tons, and production of finished rolled steel at the rate of about 29,000,000 tons. The production of pig iron has been a surprise for months, or ever since it passed a rate of 36,000,000 tons, representing approximately the estimates made of the existing capacity, based on performance the last time the industry was really active. The blast furnaces have outdone themselves. A large part of the excess production appears to be due to the fact that many furnaces have been provided with larger hearths, the change bringing about a larger output without a corre-

sponding increase in either the air or coke supplied. There was a time when predictions were made that on account of the heavy building of open-hearth furnaces without the erection of a corresponding number of blast furnaces a shortage in pig iron would occur before a shortage in steel, but the history of the market to date is that finished steel products have advanced an average of \$20 a net ton while pig iron has advanced an average of \$5.50 a gross ton. Comparisons made for the top prices of 1907, 1909 and 1912 show advances in pig iron not dissimilar to the advances in steel.

Pig Iron

The extreme dullness that characterized the pig-iron market for about two months has been suddenly broken in the past fortnight, with respect to steel-making iron. There were large purchases in the East, followed by several important purchases in the Central West, and in the latter region there was also a fair turnover in northern and southern foundry iron, the movement to date representing possibly about a quarter million tons. Prices have not advanced definitely, but consumers have become much more interested. The balance between production and consumption is a very delicate one, with few idle furnaces that are at all fit, and much open-hearth steel capacity under construction. The steel works have small stocks, but may conclude that in such uncertain times as these, and with steel prices advancing by leaps and bounds, it would be prudent to build up reserves. In some quarters there are predictions that pig iron will advance by leaps and bounds, once buyers conclude to act against the possible dangers, and it may be noted that while the furnaces have passed through an apparently trying period of market stagnation they are decidedly reserved about selling. We quote: No. 2 foundry iron, delivered Philadelphia, \$19.75 to \$20.25; f.o.b. furnace, Buffalo, \$18 to \$18.50; delivered Cleveland, \$18.80; f.o.b. furnace, Chicago, \$18.50 to \$19; f.o.b. Birmingham, \$14.50 to \$15; f.o.b. valley furnaces, 95 cents higher delivered Pittsburgh; Bessemer, \$20; basic, \$18; forge, \$18; malleable, \$18 to \$18.50; No. 2 foundry, \$18.50.

Ferromanganese is extremely scarce, bringing \$225 to \$250 for small prompt lots, while the contract price for English, second half or fourth quarter, is \$150, with some English producers not quoting at all.

Steel

The demand for unfinished steel has broadened somewhat, as premiums are obtainable for some descriptions of finished steel, the regular mill prices on finished steel, for forward delivery, not being high enough to justify finishing mills paying prices that would be asked for unfinished steel in the open market. Such mills, are, of course, moderately well covered by contracts. As fairly representing the market in general \$35 may be quoted for Bessemer and \$38 for open-hearth, either billets or sheet bars, f.o.b. maker's mill, Pittsburgh or Youngstown. Rods have advanced to \$50, for deliveries beginning a few months hence, and a few sales have been made at this remarkable figure, which is higher per pound than the regular market on plain wire.

Finished Steel

Regular prices given below are f.o.b. Pittsburgh, unless otherwise noted, and for delivery at mill convenience, the higher in a range of prices being for early delivery of small lots.

Rails, standard sections, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 2.35c. to 3c.

Structural shapes, 2.25c.

Steel bars and bands, 2.25c. to 2.75c., base; steel hoops, 2.50c., base.

Iron bars, Philadelphia, 2.409c.; Pittsburgh, 2.20c. to 2.30c.; Chicago, 1.90c. to 2c.

Plain wire, 2.15c., base; galvanized wire, 2.85c.; wire nails, \$2.30, base; painted barb wire, 2.45c.; galvanized barb wire, 3.15c.

Sheets, blue annealed, 10-gage, 2.65c. for Bessemer, 2.75c. for open-hearth; black, 28-gage, 2.60c.; galvanized, 4.75c. to 5c. basis.

Tin plate, \$4 to \$4.25 for 100-lb. cokes.

Steel pipes, 3/4 to 3-in., 75 per cent off list; galvanized, 59 1/2 per cent off list.

Boiler tubes (less than carloads), 64 per cent off list for steel, 60 per cent off list for iron.

Structural rivets, 3c.; boiler rivets, 3.10c.; cold rolled shafting, 40 to 35 per cent off list; cold rolled strip steel, 4c., base.

Continuous Operation of Engine-Driven Electrolytic Generators

The following table gives the number of hours of operation and the percentage of time that generators were in service at the Raritan Copper Works, Perth Amboy, N. J., from August to December, 1915.

Month	Engine No. 1			Engine No. 2		Engine No. 5		Engine No. 6		Per Cent Total All Engines
	Total Hours in Month	Hours in Operation	Per Cent	Hours in Operation	Per Cent	Hours in Operation	Per Cent	Hours in Operation	Per Cent	
Aug.	744	662	89	575.25	77	740.25	99.7	739	99.2	91.5
Sept.	720	719.5	99.9	705.25	98	703	97.6	715	99.4	98.6
Oct.	744	713.25	96	718	96.5	736.5	97.5	724.6	97.5	97
Nov.	720	691.25	96.1	698	97	696	97	683.6	95.0	96
Dec.	744	732.6	98.5	733.25	98.5	740.5	99.8	742.25	99.9	99
	3672	3518.35	96.0	3429.75	93.4	3606.25	98.5	3604.35	98.2	96.4

The engines are four-cylinder, triple-expansion, Corliss size 21, 38, 44 and 44 by 48, driving 900-kw. generators and were built by the Nordberg Manufacturing Co., Milwaukee, Wis.

The engines, as noted in the table, operated in most cases over 95 per cent of the time, averaging out of the total time in five months 96.4 per cent continuous operation. The time lost was for the most part in keying up and taking up lost motion in valve gears.

The chief engineer of the Raritan Copper Works is Mr. George L. Fales, to whom a large share of the credit for this operating record is due.

Non-Ferrous Metal Market

Copper.—The strained situation in copper continues. The prices here are the highest since 1873. Producers are unable to supply any copper before April or May and in some cases later. Third quarter deliveries are being contracted for. July and August deliveries are quoted at 27 1/4c. with spot at 28c.

Tin.—A rise of 2 cents per pound has been recorded and Straits tin is now quoted at 43.25 f.o.b. New York. The market is very irregular and no consistent demand has arisen although good buying takes place spasmodically. Arrivals up to the 25th were 3752 long tons.

Lead.—Lead still remains in its strong position and in view of the reported demand and sales which are hard to verify the advance made on the 14th to 6.30, New York, was very conservative. This price now rules although another advance would not be surprising.

Spelter.—Spelter is firm and higher. Third quarter is offered at 16 1/2c. eastern St. Louis. Second quarter is

offered at 18c, April at 19c and March at 20c, while spot is quoted at approximately 21c.

Other Metals.—Aluminium is scarce and has risen to 60-61c. There is no relief in sight. Antimony is also hard to obtain as it is claimed that seven-eighths of the arrivals are delivered on contract. The American Daily Metal Market gives the spot price for American, Chinese and Japanese as 43.50—44.50. Silver is quoted at 57. Platinum remains normal at \$88 to \$100 per ounce, while quicksilver is quoted at \$275 to \$290 per flask.

New York Meeting of American Institute of Mining Engineers

The one hundred and twelfth meeting of the American Institute of Mining Engineers held in New York City from Feb. 14 to 17, was a great success and very well attended. The newly elected officers as announced at the business session are Dr. L. D. RICKETTS, president; Karl Eilers, J. MacNaughton, T. B. Stearns, C. F. Rand, C. W. Goodale, E. Ludlow and G. B. Barron, directors. The amendment to the constitution raising the dues from \$10 to \$12 has been adopted. The business session was opened by the masterly presidential address of the retiring president, Mr. W. L. Saunders.

For the arrangement of an unusually attractive program of entertainments and for the vigor with which everything possible was done to make the visitors feel at home and happy, the local committee and its genial chairman, Dr. David H. Browne, deserve the highest praise. The four issues of the *Daily Fume*, published by courtesy of the *Engineering & Mining Journal* furnished much amusement and were greatly appreciated.

The smoker held Tuesday night was a most enjoyable affair and everyone who attended it was enthusiastic in his praise. Mr. L. Addicks had started the arrangements, but sickness prevented him from being present, and the affair was in charge of Mr. David H. Browne and Mr. T. T. Read. There was a most remarkable speaking doll, presented by Mr. Stearns, some grand poetry by Colonel Hay, a metallurgical cow, demonstrated by Mr. Browne, songs, refreshments, and last but not least, a really wonderful experimental lecture on flotation by Mr. Gilbert Rigg, besides a few speeches in more serious mood by some of the oldest members of the Institute. The annual banquet followed by dancing was held on Wednesday night at the Hotel Astor, while the excursion on Thursday on board of the Dolphin was enjoyed by about 200 gentlemen and 100 ladies; despite the inclemency of the weather a delightful time was had by all and many interesting features of the Brooklyn Navy Yard and Sandy Hook proving ground were witnessed. At Sandy Hook a mine was fired but owing to the fog it was not possible to fire the big guns.

The technical sessions were held according to program and all of them quite well attended.

The Relation of Clay to Ore-Dressing and Cyanidation

The presence of clay in so many ores makes a careful study of its relation to metallurgical processes a matter of great importance. A recent contribution on the subject is made by Mr. A. W. ALLEN in *Bulletin* No. 135, Inst. of Min. & Met. Empirical knowledge on the subject of clays in ore-treatment has been gained from the difficulty of settlement, dewatering and filtration, the low recovery of metal, and the problems encountered in classification as a result of the decrease in fluidity of the pulp. The customary explanation has been that oxygen has been absorbed during weathering, resulting in decreased solution-efficiency in cyanide

solutions. Later studies have shown the difference between colloidal and non-colloidal clay, and in the former material is recognized the source of much of the trouble in ore treatment. The author confines his discussion to the properties and influence of colloidal clay.

The absorptive powers of clay depend on their colloidal or non-colloidal condition, the former being highly absorbent and the latter practically non-absorbent. The change may be brought about by weathering, when non-absorbent, non-colloidal clay will change to the other form. Adsorption is a different phenomenon, and refers alone to surface concentration of a substance which clay has removed from a solution with which it is in contact. Adsorption undoubtedly occurs with colloidal clay, and metals may be adsorbed. The adsorptive nature of colloidal carbon, which has recently been prepared, when brought into contact with gold-bearing cyanide solution, might well form the basis of research.

The adsorption of metallic gold is an improbability when consideration is paid to the fact that the gold-potassium-cyanide compound is dissociated in the presence of water into K ions and AuCy₂ ions. If the latter act as electrolytes by which gold is deposited in place of calcium, then the action is the result of milling in gold-bearing cyanide solution in place of alkaline water, and may be suggested as an explanation to account for the experience of Hutchinson, which is borne out by myself and others, that treatment, after crushing in cyanide solution, necessitates a longer time for the recovery of the gold than is required when the ore is crushed in water and given a preliminary alkaline treatment.

It is also interesting to note that the problem of clarification of solutions after milling-in-cyanide is invariably obtrusive, whereas after milling-in-water trouble is seldom experienced in this direction. In other words, the electrolytic value of gold-bearing cyanide solution is inferior to that of lime water; and when once the slime particles are charged with the former no addition of lime will materially hasten coagulation.

A further and perfectly reasonable assumption may be made, that the gold in the finest condition and associated with the ore may be in the colloidal state. Any clay may actually absorb gold either during or after the process of water absorption. Marshall and Welker have shown that colloidal aluminium hydroxide in the form of a thin jelly is capable of completely absorbing gold from its colloidal solution. This aspect of gold absorption may not need more than passing mention, although it may have a greater bearing on gold recovery processes than we are inclined to admit at the present time.

It is more than likely that gold and silver compounds will be absorbed into the structure of the colloid. Their complete recovery by washing may be either impossible or impractical. Hence our present-day ideas as to the method of distinguishing between dissolved and undissolved gold and silver may have to undergo considerable modification. Metals which cannot be rapidly washed out from colloidal clay may not necessarily be undissolved; and, indeed, it is more than probable that they were, in part at least, first dissolved and later absorbed. This fact is borne out by the results of concentration experiments on slime residue, which have failed to isolate any portion of the material having a higher metal content than any other.

This matter of absorption has a direct bearing on the subject of displacement of dissolved solution from slime pulps.

In wet processes of ore reduction, and when clay compounds are milled and treated in a cyanide solution containing gold, it would seem probable that an absorption of such solution occurs in the honeycomb cells of

the colloid, and that subsequent displacement of this metal must necessarily occupy a much longer time than did its absorption. The absorption is due to direct imbibition, but displacement under normal conditions is probably due to a slow-acting osmotic pressure when the colloid slime is surrounded with wash solution or water. It is also probable that any absorptive equilibrium is only temporary under such conditions, and that cell content varies with the composition of the surrounding medium.

The question arises as to the relative merits of a slow decantation as compared with a rapid filtration process for the removal of the dissolved metal. It would seem that a combination of the two, in the order stated, would be the most efficient.

It is generally recognized among metallurgists that a considerable time of contact is necessary in washing operations with certain classes of ores; and that theoretical displacement figures do not hold good in practice. From what has already been said, it is apparent that time of wash should not always be based on estimates of gold in solution which is apparently dissolved, as compared with gold associated with the ore which is apparently undissolved. In practical work it is generally found that, although the metal which has been dissolved may be apparently replaced fairly rapidly by ordinary means, a further abstraction of metal from ore occurs after prolonged contact with wash solution. This fact would furnish additional evidence that the gold solution so recovered is, in part at least, being drawn from the cells of the colloid slime, and not merely washed off the surfaces of the slime particles.

If we admit the absorptive nature of colloidal clay, we must relegate the phenomenon of adsorption to a position of less prominence than it has hitherto been afforded.

The decrease in fluidity of an ore pulp in wet crushing operations due to inclusion of clay has been observed to have ill effects on the efficiency of classification and concentration. The author suggests the benefit of desliming prior to classification, as well as the use of vertical sided settlers instead of spitzkasten, and vertical sided classifiers instead of cones to prevent the accretion of viscous clay on the sides of the vessels. He also cites the following experience with the settling of a clay pulp: The ore contained considerable clay, both intimately associated and as pellets and balls of plastic material. As the amount of colloid material increased the thickening efficiency of the settlers decreased, and as soon as fine slime commenced overflowing the thickeners all dewatering had stopped and the underflow contained as much moisture as the feed. Classification became completely disorganized and fine sand was so buoyed by the viscosity of the pulp that traversed the radius of the thickeners and overflowed. The particles of clay were in the gel form, and no addition or reduction in the amount of lime had any appreciable effect in hastening settlement. Failure to settle was due to the absorption of large amounts of water by the clay, and although the clay entered the mill as unavoidable waste it left in the residue carrying gold that could not be recovered by ordinary washing methods.

The foregoing ill effects of colloids were corroborated experimentally as follows:

A sample of colloid slime, free from sulphides or organic matter, and carrying neither gold nor silver, was obtained. This was finely pulverized and agitated for six hours with an alkaline cyanide solution of normal cyanide content, and carrying 6.6 dwt. of gold per ton. At the end of this time the pulp was divided into two parts. One portion was drained of surplus solution until the slime carried a moisture percentage of 75, care-

fully dried, and assayed entire. The result of the assay was 8.2 dwt. per ton, which showed an adsorption and absorption of, approximately, 3.25 dwt. per ton.

The other portion was thoroughly washed with water by numerous decantations. The excess wash was then removed as far as practicable and the residue carefully dried and assayed. The result showed a gold content of 1.8 dwt. per ton.

Three separate samples of the same material were then agitated with alkaline cyanide solution of graduated gold content. After settlement the supernatant solutions were filtered and assayed, and were found to have lost an amount of gold which was in proportion to their original gold content.

If experiments are made with colloidal clay a number of points are noticeable with regard to the question of settlement. The first of these is that coagulation does not take place until after a definite minimum concentration of lime has been reached in the solution. This point of coagulation is generally marked by a distinct color change—a characteristic of colloid transition from the sol to the gel form. An iron-stained slime will lighten in color as soon as the critical point is reached, and the change is often so marked that mill men adopt it as an indication that a sufficiency of lime has been added.

The second point to be noticed is that settlement is slow at all times, but increases from minimum to maximum in direct ratio to the concentration of the lime in the solution. This rate of settlement is hindered if an excess of lime is added.

If caustic soda is used in place of lime we find that it is of considerably less value as an electrolyte; also, that a proportion of the colloid is not precipitated whatever concentration of the solution is aimed at.

In perfectly neutral solutions of colloids in the emulsoid form electrical action is almost absent. In ordinary work, such as the operation of the cyanide process, neutral solutions are seldom or never found; hence we may assume that coagulation and settlement are controlled by electrical action. It will, therefore, be mundane to consider briefly the factors governing the situation.

Lime is generally used as a neutralizer to counteract latent or formed acidity, and it is also used as an electrolyte to ensure coagulation and assist settlement. We have seen how it may and probably does act as a coagulator. This is doubtless due to the combination of the calcium ions with the slime particles. We also know that an excess of lime hinders settlement. This is due to the reduced conductivity which follows concentration of the electrolytic solution.

In summarizing his experience and work the author finds that a complete extraction of gold from even the finest slime is impracticable; that the cyanidation of accumulated clay slime often results in a lower extraction than would have been obtained had the slime been treated directly as made; that the milling a clayey ore in a gold-bearing cyanide solution invariably necessitates longer time for treatment and results in a higher residual metal content than would have been the case had it been milled in alkaline water; that the facts adduced indicate the high absorptive power of colloidal clay, enabling it to retain liquids and dissolved salts. Adsorption may occur during treatment, but the main loss is due to absorption. Non-colloidal clay is only slightly absorbent; colloidal clay, highly absorbent; burnt clay, after the colloidal envelope has been destroyed, practically non-absorbent. The weathering of clay slime should be avoided unless it is desired to decompose some refractory mineral, and clay slime should be given an extended time of contact with wash solution.

The Effect of Temperature on the Formation of Olefins from Petroleum at Atmospheric Pressure

BY GUSTAV EGLOFF AND THOMAS J. TWOMEY

It is well established that the cracking of petroleum or a high boiling fraction from petroleum in the gas state yields, besides carbon and gas, cracked oil which has a different composition than the material subjected to decomposition.

For the main part its constituents are the four types of hydrocarbons: (1) paraffins; (2) unsaturated compounds—olefins and acetylenes; (3) naphthenes and (4) aromatic compounds. The occurrence of the latter, however, depends necessarily on the conditions of the cracking. The extent to which any one of these classes may be formed is governed by the factors resulting in the decomposition of the original oil, such as nature of the oil, temperature, pressure and time of reaction which is itself controlled by the rate of flow into the heated zone and by the size of the cracking area. Of all these, temperature has perhaps the largest influence and gives the greatest variations in the amounts and in the character of hydrocarbons present in cracked oil. In a previous communication¹ its effect on the formation of the aromatic type—benzene, toluene, xylene, naphthalene and anthracene—was shown. Since it was found that certain temperatures were not only required for the formation but also resulted in definite relationships between these compounds, it was deemed of sufficient importance to investigate still further the influence of the same degrees of heat on the production of another group of hydrocarbons in the same cracked oil—notably the effect on the formation of unsaturated compounds.

According to the available data in the literature the nature of these unsaturated hydrocarbons have been investigated sufficiently to show in a general manner those common to a cracked oil. Thorpe and Young² found that paraffin on being distilled under pressure at a high temperature decomposed into liquid compounds of the methane and ethylene series. Among the latter were included amylene, hexylene, etc., up to nonylene. Gawalowski³ has found recently that paraffin on prolonged heating changed into gaseous and liquid products, which in both cases belonged to the ethylene and acetylene groups. In the investigation of the "hydrocarbon" resulting as a by-product in the manufacture of Pintsch Gas, Armstrong and Miller⁴ found olefins—ethylene up to nonylene and also crotonylene. Lewes⁵ states that the recovered tar obtained by the cracking of Russian petroleum contained hexylene and heptylene. Kramer and Spiker⁶ distilled a lubricating oil (Baku) under pressure and identified olefins in the distillate which was recovered.

From the work of these investigators it appears that the cracking of high boiling fractions of petroleum give low boiling fractions which among other substances contain unsaturated compounds, mainly those of the olefin series. The research to the present date does not seem to show that members of the acetylene series are formed to any great extent.

No specific data could be found in the literature concerning the direct effect of temperature on the unsaturated hydrocarbon formation. Hall⁷ states, however, "I can say with all assurance that high temperature makes for high unsaturation." This conclusion was derived

from experimental evidence obtained in the operation of his process.

If in cracking an oil by distillation under pressure, the pressure effect may be translated into terms of temperature, a few more examples of the influence of temperature on the unsaturated formation may be had. Distillation under pressure is that type of cracking which takes place in the liquid-gas phase. In this system increased pressure is due to increased temperature. Hence, results obtained by cracking under increased pressure correspond in a manner to those found under increased temperature conditions when the cracking is conducted entirely in the gas phase. In the Burton process the distillate is condensed under pressure because pressure decreases the amount of unsaturation. A statement presented to the United States Patent Examiner gives the sulphuric acid absorption of the Burton distillate as 20.2 per cent and iodine number as 97 against 49.4 and 200 respectively on a similarly cracked distillate condensed without pressure. Brooks⁸ found that cracking Oklahoma petroleum under pressure decreased the refining losses in the gasoline cut besides increasing the amount of gasoline formed. The data constitutes the ground for United States Patent 1,101,482.

Scope of the Investigation

In the present paper it was not the intention of showing the influence of temperature on the individual unsaturated formation, but rather on the total formation in certain distillation cuts. In the analysis of cracked oil for aromatic hydrocarbons produced by cracking a distillate or gas oil derived from a Pennsylvania crude petroleum in the gas state at temperatures 450 to 800 deg. C., distillation cuts were made to 95 deg. C., 95 to 120 deg. C., 120 to 150 deg. C., 170 to 230 deg. C., 230 to 270 deg. C., and 270 deg. C. to Tar.

The object of this investigation was to point out the unsaturated hydrocarbon formation in these cuts. From a combination of values, it was also possible to show: (1) the effect of temperature on the unsaturation in the recovered oil to 95 deg. C., 95 to 120 deg. C., 120 to 150 deg. C., 170 to 230 deg. C., 230 to 270 deg. C., 270 deg. C. to tar; (2) the unsaturated formation in the gasoline cut—to 150 deg. C. This method of procedure allows one to follow the thermal effect on the formation of the unsaturated hydrocarbons in the cuts and also the extent to which the original paraffin oil on being thermolized decomposed to lower and equally high boiling olefins and similar compounds.

Experimental Part

A distillate or gas oil, boiling between 250 and 350 deg. C., derived from a Pennsylvania crude petroleum was cracked in the gas state by passing through a steel tube at atmospheric pressure. Experiments were run at the following temperatures: 450, 500, 550, 600, 650, 700, 750 and 800 deg. C. The per cent of recovered oil obtained, the gas formation, the specific gravity of the recovered oil, the aromatic content and other data will be found in a previous communication.⁹

The recovered oil from each experiment was distilled using an efficient fractionating column for the lower boiling constituents, and final cuts were made to 95 deg. C., 95 to 120 deg. C., 120 to 150 deg. C., 170 to 230 deg. C., 230 to 270 deg. C. and 270 deg. C. to tar.

The per cent of unsaturated compounds in these cuts was determined by means of 95.0 per cent sulphuric acid. The following method of procedure was used: Ten cc. of oil was measured by means of pipette into a Babbcock milk bottle, the neck of which was calibrated in

⁹ Loc. Cit.

tenths of a cubic centimeter, one cc. of 95.0 per cent sulphuric acid was added from a burette. The bottle was shaken for five minutes, cooling at the same time in order to avoid heating. Following the same procedure, two, three and four cc. of acid were added. The bottle was centrifuged for three minutes, enough sulphuric acid added to bring the unabsorbed oil upon the scale on the neck and the bottle again centrifuged until no further increase of unabsorbed oil was obtained. The reading of the amount of unabsorbed oil was made, and the unsaturated formation was found by difference.

No extreme accuracy is claimed for the method. It is well recognized that the determination of certain hydrocarbons is beset with particular difficulties because the chemicals used overlap other groups to a greater or lesser extent. In this particular case, the concentrated sulphuric acid, by means of which the unsaturated hydrocarbons were determined, attacks the low boiling aromatics, the naphthalenes and even the paraffins. For

this reason, the method does not lay claim to any great accuracy. All that is claimed is that the method was of sufficient accuracy to bring out in unmistakable terms the effect of temperature on the unsaturated formation.

The first determination for unsaturation was made on the oil used for the cracking experiments. Concentrated sulphuric acid did not have any effect upon it.

The determination of the unsaturated compounds in the cuts was simple to make, although great care had to be taken with the determinations of the lower boiling fractions. The addition of even a small quantity of sulphuric acid produced great heat. For this reason, the oil was cooled before the addition, and immediately held in running cold water to avoid heating. The acid produced a black red sludge, the depth of color of which depended on the amount of unsaturated compounds present.

The experimental results obtained are all based on the determinations in the different cuts. From these data it was possible to bring out the following, which are shown in tables and in figures:

1. The effect of temperature on the per cent of unsaturation in the cuts to 95 deg. C., 95 to 120 deg. C., 120 to 150 deg. C., 170 to 230 deg. C., 230 to 270 deg. C. and 270 deg. C. to tar.

2. The effect of temperature on the per cent of unsaturation in the gasoline cut to 150 deg. C.

3. The effect of temperature on the percentage of unsaturated compounds in the recovered oil in the cuts to 95 deg. C., 95 to 120 deg. C., 120 to 150 deg. C., 170 to 230 deg. C., 230 to 270 deg. C. and 270 deg. C. to tar.

Discussion of Experimental Results

A. THE EFFECT OF TEMPERATURE ON THE FORMATION OF UNSATURATED COMPOUNDS IN THE CUTS TO 95 DEG. C., 95 TO 120 DEG. C., 120 TO 150 DEG. C., 170 TO 230 DEG. C., 230 TO 270 DEG. C. AND 270 DEG. C. TO TAR

It must be borne in mind that the original oil which was cracked boiled between 250 and 350 deg. C., and was not attacked at all by sulphuric acid. Decomposition by heat produced low boiling fractions and changed the original fraction. This amount of decomposition was proportional to the temperature employed.

Fig. 1 brings out the decomposition to low and high boiling unsaturated hydrocarbons. The data should be divided into two parts, (a) the per cent of unsaturated compounds in the cuts up to 150 deg. C., and (b) the per cent of unsaturated hydrocarbons in the cuts from 170 deg. C. to tar. Each set has its characteristics. In the cut below 150 deg. C., the per cent of unsaturation reached a maximum at 600 deg. C. in all three cases, and then decreased to practically zero at 800 deg. C. In the cuts above 150 deg. C., the amount of olefins and similar compounds attacked by sulphuric acid increased with temperature. The determinations could not be made at the two upper temperatures 750 and 800 deg. C. as these cuts consist almost entirely of the solid aromatics, naphthalene and anthracene. It is considered that a similar maximum would have been obtained provided these could have been made, and that the unsaturation would have decreased at 800 deg. C.

These data may be used to show the effect of temperature on the formation of unsaturated compounds such as olefins, and more especially the course of the cracking reaction. The original high boiling oil on thermolization splits to lower boiling fractions containing paraffins, naphthenes, olefins and aromatics with the production of the latter depending on the conditions. In the low boiling fractions at the low temperatures, one only expects to find paraffins, naphthenes and unsaturated compounds. From the data, it appears that the

amounts of saturated compounds such as paraffins and naphthenes at 450 and 500 deg. C. predominate in the cut to 95, and likewise in the other two low boiling cuts. Increasing the temperature of the reaction increased the percentage of olefins in each cut. This was accompanied by increased formation of aromatic compounds¹⁰, and hence the paraffin and naphthene content must have decreased. At the higher temperatures, olefins and aliphatic saturation decreased, and aromatic compounds predominated in each cut.

The course of the reaction with temperature of the decomposition to low-boiling products may be represented by

High-boiling paraffins →
 Low-boiling paraffins →
 Low-boiling unsaturated hydrocarbons →
 Low-boiling aromatics.

Besides cracking the starting oil to low-boiling fraction, the reaction has also changed the character of the oil, and as the heat effect increases the amount of unsaturation increases, although it is not so large as was found in the lower boiling fractions. These facts are brought out from the degree of unsaturation in the high-boiling fractions, 170 deg. C. to tar. While the data do not show, it is to be expected that this formation would also reach a maximum and then decrease with the resulting formation entirely of naphthalene and anthracene in these cuts. The change with temperature on the character and composition of the high-boiling cuts may be expressed as

High-boiling paraffins →
 High-boiling unsaturated compounds →
 High-boiling aromatics.

B. THE EFFECT OF TEMPERATURE ON THE PERCENTAGE OF UNSATURATED COMPOUNDS IN THE GASOLINE CUT TO 150 DEG. C.

The total percentage of the unsaturated compounds in the gasoline cut was found by combining the percentages in the cuts which made up the fraction to 95 deg. C., 95 to 120 deg. C., 120 to 150 deg. C. For 450 and 500 deg. C. an estimation had to be made, since values were not obtained for the cut 95 deg. to 120 deg. C. at 450 deg. C., and 120 to 150 deg. C. at 800 deg. C. The results are similar to these in the distillation cuts which make up the fraction. The unsaturation, represented by 28.0 per cent at 450 deg. C., reached a maximum of 44.0 per cent at 550 deg. C., and declined to practically zero at 800 deg. C., the value being only 5.0 per cent.

Aside from bringing out the successive steps of the reaction resulting in the formation of the lower boiling hydrocarbons, the data are interesting in their relation to the making of gasoline by cracking of petroleum at atmospheric pressure. From the amount of unsaturation formed, it would not be advisable to crack an oil similar to the one employed in these experiments for gasoline, due to the high degree of unsaturation in the gasoline obtained. The refining losses, represented by the percentage of unsaturated compounds, would be excessively heavy, and enough to make a commercial operation prohibitive at atmospheric pressure. Although at higher temperatures the amount is small, it is due to the large percentage of aromatic compounds, benzene, toluene and xylenes, which have been formed, and which would not be used for gasoline at the present time.

If the effect of temperature in the cracking of oil in the gas phase may be compared to the effect of pressure in the cracking in the liquid gas phase, it would appear that the data from the Burton process and the results

obtained by Brooks¹¹ are similar to those found in the present research. The decrease in unsaturated products in which increased pressure found by them corresponds to the decreased formation with increased temperature in the present case after the maximum has been reached. There arises the interesting possibility that increased pressure in the liquid gas reaction, besides cutting down the olefin formation, produced aromatic compounds such as benzene, toluene and xylenes in the gasoline cut. There are no data to be had regarding this from the Burton process. Brooks, however, states that benzene, toluene and xylene were produced by distilling Oklahoma "reduced" oil under 100-lb. pressure, the same conditions which gave the minimum refining loss in the gasoline produced. This seems to bear out the assumption that decrease in olefin formation with increased presence is accompanied by increase of aromatics.

Some chemists may attribute the decrease as due to the polymerization of the olefins to naphthenes, as has been shown by Engler¹². On the other hand, naphthenes decompose very readily to aromatic compounds by dehydrogenation, a fact which has been shown by Zelinsky¹³ and others. The decrease in olefin formation may then be accounted for in two ways, which in both cases give the same end products: polymerization of the olefins to naphthenes, which in turn go to aromatics; polymerization of the olefins directly to aromatics.

¹¹ Loc. Cit.

It is difficult to interpret the general statement of Hall" that high temperatures make for high unsaturation, unless the general conditions of the cracking corresponding to those at 450 deg. C., beyond which point for 100 deg. saturation increases with temperature. Even under pressure, temperature decreases the olefin formation.

C. THE EFFECT OF TEMPERATURE ON THE UNSATURATED COMPOUNDS IN THE CRACKED OIL

Another combination gave the percentage of unsaturated compounds in the cracked oil, the data being given by distillation cuts.

As a general rule, the lower temperatures produced a cracked oil which contained the largest per cent of olefins in the lower boiling cuts. Moderately high temperatures resulted in cracked oils containing unsaturated compounds distributed through all cuts evenly. The highest temperatures gave but little in the lower boiling cuts, with indications that the same would be true of the higher boiling ones. It is regretted that data could not be obtained for these. It appears then that the cracked oil obtained by the thermal decomposi-

tion of a paraffin oil contains olefins, the amounts of which are governed by the temperature of the reaction. The formation with increase of temperature reaches a maximum, and then decreases to practically zero. Theoretically this is possible. At the higher temperatures, naphthalene and anthracene form the greater portion of the oil in addition to the pitch. These compounds are much more stable than any olefins known. And with the tendency of the reaction to produce aromatic compounds, it is not to be expected that there will be very much unsaturated formation in the cracked oils produced by the high temperatures, 750 and 800 deg. C.

Conclusions

From the experimental data it is possible to draw the following conclusions:

1. Unsaturated compounds are found in the recovered oils obtained by the cracking of a gas oil, boiling between 250 and 350 deg. C., and derived from Pennsylvania crude petroleum at atmospheric pressure, and at temperatures 450, 500, 550, 600, 650, 700, 750 and 800 deg. C.
2. With the temperature range employed, the unsaturation reaches a maximum in the lower boiling distillation cuts to 95 deg., 95 to 120 deg. C. and 120 to 150 deg. C.
3. In the higher boiling distillation cuts, the per cent of unsaturation increased with increase of temperature as far as data was obtained, with indications that a decrease would have been obtained at higher temperatures.
4. In the gasoline cuts, to 150 deg. C., the unsaturation reached a maximum and declined with increase of temperature.
5. In the cracked oils obtained, the total unsaturated formation increased with temperature with indications again that a decrease would have been found at the higher temperatures.
6. The change in the composition of the lower boiling fractions of the cracked oils with increase of temperature may be represented by low-boiling paraffins to low-boiling olefins to low-boiling aromatics.
7. The change in composition of the higher boiling fractions may be expressed with increase of temperature as follows: High-boiling paraffins to high-boiling olefins to high-boiling aromatics.

Pittsburgh Division, Aetna Chemical Co., Pittsburgh, Pa.

Announcement of Special Lectures at College of City of New York

The Department of Chemistry of the College of the City of New York, Dr. Chas. Baskerville, director, announces a series of very interesting spring lectures to be given at 3 p. m. at the college on the following dates.

March 10—Food control in New York City (illustrated), by LUCIUS P. BROWN, director Bureau of Food and Drugs, Department of Health, New York City.

March 17—The Extraction of Radium from Its Ores (moving pictures), by Dr. CHAS. L. PARSONS, U. S. Bureau of Mines.

April 7—Chemical Control of Medical Supplies Purchased for the U. S. Army, by Lieut. D. W. FETTEROLF, U. S. Army.

April 14—Science in the Humanities, by ELWOOD HENDRICK.

May 5—The Emancipation of American Chemical Industries (moving pictures), by Dr. THOS. H. NORTON, U. S. Department of Commerce.

May 12—Food Poison (illustrated), by JAMES P. ATKINSON, Department of Health, New York City.

FIG. 3—PER CENT OF UNSATURATED COMPOUNDS IN THE CRACKED OIL BY DISTILLATION CUTS

Universal Flotation Theory*

BY C. TERRY DURELL

It seems incredible that every one of the many flotation processes are satisfactorily explained by an all-embracing theory. How can the theory of film flotation be identical with that of froth flotation? How is the theory of the Cattermole the same as that of the Callow? Thirty years ago Carrie J. Everson of Chicago described flotation as well as it can be described to-day, and it is quite evident from this description that thirty years ago a test might have been made for any of the many present-day processes using oil.

One theory will explain all processes of flotation if the essential element be the same in all cases. A process of elimination applied to each method of flotation will leave at least one essential element. This proved, there then follows the corollary that a theory that does not explain all processes of flotation satisfactorily is worse than useless as it is sure to confuse a subject already kept long in darkness by complicated litigation. Never before has litigation so retarded a science by smothering it in a cloud of secrecy. It is to be regretted that this condition has been brought about by some prominent engineers attempting to gain a world-wide control of all processes of flotation after the basic patents had expired.

The essential elements of flotation can be arrived at in two ways: (1) Investigation of conditions under which different minerals float; and (2) investigation of all different processes. In Australia, the home of flotation, more flotation experiments have been carried out than in any other country. This statement will not hold true for long judging from the present rate of advance in this country.

Kenneth A. Mickle's experiments published in the Proceedings of the Royal Society of Victoria¹ furnish the most complete record of systematic research to learn the reasons for flotation. These experiments were carried on with different metals and minerals in the laboratory and subject to the conditions met with in the several flotation processes. He tried them with water, oil, acid and alkali; hot and cold; at atmospheric and reduced pressure and in various combinations. Many of his experiments I have confirmed at the School of Mines. His experiments show that minerals at the surface or in the interior of liquids float or tend to float due to:

1. Liberation of gas contained in the liquid either by reduction of pressure or heat;
2. Generation of gas in the liquid by means of acid; or
3. Supersaturation of the liquid with gas.

He shows that minerals absorb (occlude) gas to a degree not previously suspected and that the effect of this occluded gas is that:

1. Particles are not wholly wetted by immersion in water;
2. Particles tend to float when sprinkled on a liquid surface;
3. Particles collect bubbles when heat or vacuum is applied; and
4. Particles collect bubbles evolved from a gas saturated solution.

The Swinburne and Rudorf² experiments show that "It seems necessary that the gas should be produced at the surface of the particles themselves." Many other references might be cited to show that the whole sub-

ject of flotation depends upon gas occlusion by the minerals to be floated.

As was to have been expected, Mickle showed the gas held by flotation concentrates consists almost entirely of nitrogen, oxygen and carbon dioxide. That is to say, the occluded gas was from the atmosphere.

These experiments have thus eliminated oil, acid, alkali, heat, vacuum, saturated gas solutions and the like as being essential elements of flotation. The conclusion that necessarily follows is that flotation depends on the fact that, due to the occluded gas of the mineral particles, they become entangled or caught by the surface film of: (1) the free surface of the liquid; or (2) the surface of a gas bubble; (a) above the surface or (b) under the surface.

It is well now to classify and investigate the different processes to see if a similar system of elimination will give the same results as this obtained from laboratory experiments.

Surface Tension Flotation

One of the oldest types of flotation is that which the prospector, in panning, tries to guard against. How easy it is to drain the water from the trail of fine gold in the pan and then pick it up on the surface of the water! Every vanner-man can testify as to the richness of concentrate from the settling boxes back under the machine behind the main concentrate box. This is the concentrate that dries as the belt travels down over the end of the vanner and floats on the surface as the belt dips into the water in the concentrate box. Hezekiah Bradford in his patent No. 345,951, in 1885, reverses this process by using a belt to remove the floating concentrate. It was nearly twenty years later (1904) that Macquisten used a spiral in a tube to lift and expose the pulp to the air so the metallic particles would float on the surface of the water in the tube. This was a commercial success, though oil is now used to aid the process. Henry E. Wood's machine, patented March 21, 1911 (No. 987,209), feeds dry ore gently onto the surface of water so that the metallic particles float over a lip and are saved. All of these cases come under what may be termed "surface tension flotation." Evidently the only essential feature is that the particles to be floated be exposed to air. That is, there must be a chance for gas occlusion. The selective action, which causes the metallic particles to float while the gangue particles sink, will be taken up later.

Bulk Oil Flotation

How "the virgins drew up gold by means of feathers daubed in pitch" is told by Herodotus. Thus that pitch, oil, grease and the like adhere to metallic particles with greater force than does water has long been known. This fact was first recognized in a patent (No. 483, British) to William Haynes in 1860. Under the Elmore patents of 1898 and 1901, bulk oil flotation was put on a commercial basis, although the many plants built in different parts of the world were doomed to failure because of the great quantities of oil necessary. Excessive oil is necessary, due to the little difference in specific gravity between oil and water as compared to the greater difference in specific gravity between water and the metallic concentrate. As no acid was at first used by the Elmore process, it is not an essential element to flotation.

The Cattermole patent in 1903 improves upon this by using less oil in what was known as the oil granule process. These granules were then removed in various ways either from the bottom of the container or driven to the surface by an upward current of water or gas. This was the forerunner of the present froth processes, but the only plant built was a complete failure. This

²Faraday Society paper read Dec. 12, 1905. Abstracted Eng. and Min. Jour., February 10, 1906.

was to treat 400 tons daily at the Central Mine, Australia. Everyone who has made a froth flotation test has, probably, at some time, added too much oil and seen these granules resting above the pulp at the bottom of the vessel. Some may rise to the surface of the liquid and drop back again. In the Cattermole process, soap and acid were used, but a test, as above, shows that granules will form with oil only, so these two things are not essential elements. The only bulk oil flotation plant that I examined was at the Lake View Mine, Kalgoorlie, Australia. It, like all others, was a failure so I was not able to determine if gas occlusion by the metallic particles is the essential element to the process. From the very nature of the process, oil of course is an essential element. Mickle's experiments showed that mineral particles deprived of occluded gas do not, as a rule, become coated with oil in the presence of water. The selective action necessary for this flotation will be taken up later.

Froth Flotation

In taking up these processes in detail to eliminate all but essential elements to flotation, such questions as air froth or oil froth, selective or preferential flotation, and the like will not be discussed. These things as well as the forces, adhesion, electricity, cohesion, surface tension, etc., will be taken up under other headings later. About four years ago I made a trip to Australia and studied these processes quite carefully at the largest plants then in the world working four distinctly different methods. Since then I have seen several plants operating in this country but with only one different method or machine—the Callow.

Delprat Type.—The Delprat and Potter processes were developed independently at the same time, patented in 1902, and are practically the same. This was the first commercially successful froth flotation. It has since proved unfortunate for Minerals Separation that the Fremont patent in the same year was only taken out in Italy and England. For this reason it was necessarily suppressed by the purchasers. Also processes where gas is generated by electrolysis like the Fields come under this heading.

As G. D. Delprat was general manager of the Proprietary Company at Broken Hill, his process was naturally used there. About 1000 tons were being treated daily when I studied the flotation process at this property. A "push feeder" delivered 700 pounds of ore per minute to a single spitzkasten where flotation took place without agitation except that of the upward current of hot acid solution being added at the bottom. By heating the solution with superheated steam, it was intended to work with a solution as near 80 deg. C., the critical temperature for flotation, as possible. The working solution temperature, however, was below 70 deg. C. The quick action and simplicity of the process was most pronounced. A marketable zinc concentrate was being produced with high recovery without retreating it or the tailing. The essential elements may be summed up as follows: gas, acid and heat in addition to the ore and water. The acid attacking the carbonates in the ore produced the bubbles in addition to the selective action which will be taken up under a separate heading. This gas made the bubbles for the froth, as no air was taken into the solution in any way except the little that might come in with the ore. None could come in with the solution as no jet or nozzle was used above the surface of the liquid, which would have carried air in, as will afterward be described. This solution was brought in at the bottom of the spitzkasten and, being hot, could contain but little dissolved air. Since heat was necessary, its only function was to expel occluded air from

the mineral particles the same as from liquid in accordance with the law of Henry.

Vacuum Type.—The Elmore vacuum machines were being used at the Broken Hill, British plant, although they had been thrown out from several other plants there. This was not due to unsuccessful operation but to litigation. No more than the following essential elements are necessary for the operation of the Elmore, the only successful vacuum process: vacuum (to liberate the air to form bubbles), acid, oil and alkali. Cast iron machines are used so lime is required to neutralize the pulp before it goes to the vacuum machines. The acid of course is not to generate bubbles as in the Delprat process. Therefore, the acid creates the selective action the same as in the Delprat process. In accordance with Henry's law, gas or air is liberated from the pulp by reduction of pressure to form the froth. As will be shown later, these bubbles must necessarily form on mineral particles as nuclei. The bubbles burst very readily in the Delprat process, but there is such an ebullition that any metallic particles thus dropped are caught by the bubbles below. There is no chance for this with the Elmore so the bubbles must necessarily be more persistent. In the Delprat, the bubbles are armored with the metallic particles. To make them more persistent in the Elmore, oil, in addition to the metallic particles, is used to coat them. This toughening of the froth with oil will be taken up under a separate heading.

Minerals Separation Type.—Under this heading may be grouped all processes or machines using rapidly revolving paddles or stirrers to beat air into the solution. This method of forcing air into solution beyond the point of saturation was known long before our grandmothers used it to beat eggs or whip cream. It matters not whether air be beaten by being admitted to the suction of a centrifugal pump or to the periphery under pressure or beaten in by the propeller on the vertical shaft of a mineral separation or other machine. The essential elements can be eliminated as follows: air (beaten in to supersaturation), acid, oil and heat. What is the difference whether bubbles be formed from air coming out from a supersaturated solution or from a solution subjected to vacuum? Bubbles will form on mineral particles as nuclei in either case. The acid here of course acts as in the former case. Since heat is not always used, its only function can be to assist in expelling the air from the mineral particles. The froth from these machines is the most persistent. This is due to the greater amount of slime and the better agitation to oil-coat the metallic particles. Like butter in a churn, these fine metallic particles are coagulated by the violent agitation. The mineral particles are so well oiled that an exceedingly coherent armor for the bubbles is produced. The oil films of these bubbles are extremely thin like those of other processes. Iridescent colors indicate this. The surface tension effect of the oil is added to that of the water for further toughening the bubbles.

DeBavay Process.—This, at first, appears to be a purely surface tension process. As originally patented by DeBavay, it probably was, but, as now used by the Amalgamated Zinc, Ltd., of Broken Hill, it even has the bubbles, although all the large ones are liberated before flotation commences. The same principles apply here as in any froth flotation. The clean sand is thoroughly agitated in an acid solution, washed and then again agitated in steel tanks with water to which a fixed amount of an oil mixture (mostly kerosene) has been added. The agitators in these tanks are like ship propellers and as large. This gives thorough oiling to the particles. A montejus delivers the pulp to the top

series of four each DeBavay cones. The pulp is, therefore, surcharged with air due to this air pressure, since the air dissolved by the water varies directly as the pressure. Norris has patented (No. 864,856) the idea of thus surcharging a liquid with gas, but he delivers the surcharged liquid beneath the surface of the pulp mixture. The Callow machine also uses this principle except that the air pressure is exerted on the bottom of the liquid instead of on the top as with a montejus. There are no bubbles or froth because the pulp mixture from the montejus is turned on to the apex of the cones and spreads out, flowing down the steeply inclined surfaces. The essential elements to this process are: gas (in the form of air), acid and oil. These are the same as with preceding processes. Although there is no froth, air is here the prime requisite while the acid creates the selective action. The metallic particles are so well oiled they are not easily wetted by the water while their air films and minute attached bubbles bodily lift them to the surface of the water if, by chance, they go in under instead of on the surface when they strike the water at the periphery of the cones. In a laboratory test, the metallic particles seem to jump from the bottom of a beaker to the surface of the liquid.

Callow Type.—This includes all froth flotation processes depending on the supersaturation of the liquid by air pressure in accordance with the law of Henry. The DeBavay process was taken up previous to this as it is the connecting link between this and Mineral Separation type. It (DeBavay) uses violent agitation which beats in air and also direct air pressure which supersaturates the pulp mass.

This supersaturation is caused, according to the Norris patent, by subjecting the liquid to an air pressure of several atmospheres. In the Callow machine, it is "a hydraulic pressure varying from 15 to 40 inches" that causes the liquid at the bottom of the box to absorb air beyond the saturation point of the surface liquid at atmospheric pressure. If too much air is blown into a Callow machine, the effect is the same as the air in the pachuca tank—agitation.

The bubbles composing the froth are derived from that air which was first absorbed and afterward liberated on a mineral particle as a nucleus in the same way that air, beaten into solution in a Mineral Separation machine, supersaturates the liquid and comes out in the form of bubbles. A jet of air turned into liquid pulp produces bubbles which effect no mineral attachment. They pass through the pulp as do those from excess air in the Callow cell. The essential elements for the Callow type may be picked out as follows: air (from supersaturation of the liquid), oil and acid or alkali. The oil, as shown above, aids in making a more persistent froth. It is mixed with the pulp previous to entering the machine. The acid or alkali is to form an electrolyte for selective action.

Liquid Jet Type.—Heretofore only two ways of getting air into solution have been taken advantage of to aid flotation. These, as mentioned above, are: (1) beating it in as is done in Mineral Separation type; and (2) surcharging the liquid with gas as is done in the Callow type. While experimenting at the Colorado School of Mines some three year ago, I developed a third way which is now being patented. One of the patents has been issued.

Common occurrences of this phenomenon are seen everywhere. On drawing water into a beaker, bubbles form and rise to the surface. Where does the air come from? A muddy overflow is caused in a settling tank by allowing the mill stream to be turned down into the tank from some little distance above. Froth forms and overflows. Hydraulic air compressors and

blowers are operated on this principle by turning a stream of water down a shaft or pipe. In the same way that an air film surrounds a drop of liquid so that the drop method may be used in determinations of surface tension, so does an air cylinder enclose a liquid jet. This adhesion is so great that air is carried into the liquid to the supersaturation point and it comes out in the form of bubbles.

The model I built at the School treated ore at the rate of twenty-five pounds an hour working in an acid solution with oil fed to the first cone. This type of machine produces either a scum float like DeBavay's or a thick persistent froth with well armored bubbles. The essential elements may be noted as follows: air (brought in by the liquid jets), oil and acid, or alkali.

Having classified flotation into that of (1) Surface Tension, (2) Bulk Oil and (3) Froth and subdivided Froth Flotation into the different types of (a) Delprat, (b) Vacuum, (c) Mineral Separation, (d) Callow, and (e) Liquid Jet, there are found only these few essential elements as follows: air or other gas, acid, heat, vacuum, oil and alkali. These only are necessary in addition to the liquid and the ore. It is possible to still further eliminate.

Essential Elements

Cold solutions were seen to be used with some processes. Therefore heat is not an essential element to flotation. Vacuum is used in the one type to produce the gas so it is not essential to flotation. Oil is not always used in froth flotation so it is not an essential element to any except bulk oil flotation. This fact is also shown by the new process of Louis A. Wood. An alkali is used in one case to neutralize the excess acid and in others in place of an acid. Either an acid or an alkaline solution will do and, from the amounts used in mill solution, it is seen that extremely dilute solutions are effective. That is, complete ionization exists and the effect is that of an electrolyte. By this process of elimination there is left the essential elements as follows: air for surface tension flotation; oil for bulk oil flotation; and gas and an electrolyte for froth flotation.

It is seen that the gas, to form bubbles in froth flotation, can be generated chemically or electrolytically within the pulp mass or it can be (1) beaten in with stirrers, (2) forced in by pressure (that of the atmosphere or greater), or (3) carried in by jets. Something more than mere bubbles of gas within the pulp mass is necessary to make froth flotation effective.

The mineral particles must either be attached to the bubbles or the bubbles must be attached to the mineral particles. It amounts to the same thing whether the bubble be attached to the solid or the solid attached to the bubble. Since a bubble carries with it a surface film of liquid, the mineral particle must be caught by this surface film in froth flotation or caught by the free surface of the liquid in surface tension flotation. The necessary conclusion then is that some inherent property of the mineral particle itself is the cause of its resting on the surface of the liquid in the one case or on the surface of the bubble in the other. If it were possible to attach a mineral particle to a bubble already formed by some physical, chemical or electrical force, then it might be possible that surface tension flotation and froth flotation are in no way related, and that bubble attachment is in no way dependent upon some property of the particle itself. It is a well known fact, however, that no such attachment can take place to bubbles that are already formed.

A stream of compressed air turned into a pulp mass in a perfect float condition can not effect flotation, as

is well known by every one who has tried it. The bubbles not only rebound from one another but the mineral particles show no tendency to adhere and the bubbles come to the surface without the mineral particles. This is due to the surface film, which phenomenon will be taken up later, when it will be shown that there can be no adhesion between this liquid film and the mineral particle, be it either wetted with oil or water. There is no reason for any chemical affinity.

Electrical Theory Insufficient

In an electrical field, it is possible for bubbles to be electro-negatively or electro-positively charged. There is no reason why these charges might not be reversed at will by varying the field. Also it is a well known fact that mineral particles can be electrically charged and this is taken advantage of in electrostatic concentration, Cottrell dust precipitation, clay separation, etc. It is also shown in colloidal work that, under the same condition, some minerals are negatively charged while others have an opposite charge. It is upon these facts that electrical theories of flotation are based. Assume that the particles of metals, sulphides, tellurides, arsenides and the like "have charges of one polarity (positive), and that non-floatable particles have charges of the opposite polarity (negative)," and also that the bubbles are negatively charged. Witness, then, the metallic particles jumping for and clinging to the bubbles. A beautiful theory if it were true and would explain all connected with flotation.

In the first place, flotation is not dependent upon an electrical field as is electrostatic concentration, dust precipitation, Botho Schwerin's electro-osmotic process and others. It would also be possible to attach mineral particles to bubbles already formed by the assumption of an electrical theory. So far, these electrical theories have considered oil as an essential element to flotation, which, as shown above, is not the fact. If a slight change in the strength of the electrolyte will change the polarity of quartz, calcite and the like so as to cause them to sink, when before they were floating, why will it not also change the polarity of some metallic particles so as to create a preferential flotation? No. It is far better to make a theory conformable to the facts than to try to ignore and twist facts to conform to some of the present electrical theories. Since there is no known way to attach mineral particles to bubbles already formed, bubble attachment depends directly upon some property of the particle itself. This property must then be the same for particles floating in either a surface tension or a frothing machine. As shown by Mickle's experiments, this must be due to gas occlusion.

Why is it then that no solid can be floated unless it contains occluded gas? A particle once wetted with the flotation liquid tends to sink as there is no surface tension effect tending to float it. Water is always used as the flotation liquid as it is the cheapest and has the greatest surface tension of all liquids except mercury. If all gases be driven from a solid, water will enter the pores and adhere to its surface. No surface tension effect can be then exhibited towards it for the reason that it is then as part of the water. Thus a force of adhesion predominating, flotation can not take place. This truth is not so readily seen when the particle is below the surface of the water and an attempt is made to float it by means of a bubble. The surface tension of the liquid film surrounding a gas bubble is much greater than the adhesive force of the gas for a solid. The gas is, in this way, firmly held within the enclosing liquid film and attachment between it and a solid cannot take place. As has been shown above, it

is only the gas that comes into being within the pulp mass that is of any value in flotation. In other words, this nascent gas is attracted by the gas at the surface of the solid. A cohesive force exists between the molecules of the gas at the surface of the solid and those in the immediately surrounding liquid so that the solid becomes a nucleus for the formation of a bubble from the nascent gas of the liquid. As shown above, there are three mechanical ways of forcing air or a gas into solution. Also there are three methods of expelling it: (1) supersaturation so that the excess gas is driven out; (2) heating to increase the volume and drive some out; and (3) reduction of pressure.

Role of Occluded Gases

The same cause that tends to supersaturate a liquid with gas will evidently tend to supersaturate a solid with this same gas if this solid be within the liquid. Also the dissolved gas will evidently be expelled from both the liquid and a solid within it by the same force—one of the above. Due to adhesion, the gas, as it is expelled, tends to condense on the solid or increase the amount of absorbed gas. Lest confusion arise, it may be stated that "absorb" is here used in the sense of being one of the three ways that solids hold gases. With sufficient condensation, a bubble will form on the surface of the solid from these molecules as they collect.

As a logical sequence from the above reasoning, solids with high occlusive power for gases should have a greater tendency to float. Hezekiah Bradford was the first to recognize this fact.³ "These floating particles appear to possess some peculiar qualities which repel water from their surfaces, especially when the particles are exposed, even momentarily, to atmospheric air." It is only necessary to look into the subject of ore deposition to learn the reason why metallic particles occlude gas more readily than other minerals. Chemical affinity assists in this occlusion of air and carbon dioxide, which eventually change the sulphides and like ores into sulphates, carbonates, oxides, etc. This greater power of occlusion is a cause of selective flotation.

Selective flotation is here used as a general term in contradistinction to preferential flotation, an accepted term to designate the separation of minerals that ordinarily float together. Horwood accomplishes this by a roast that oxidizes some sulphides and not others. The same effect is accomplished by others by coating the sulphides not desired in the concentrate. Leslie Bradford uses a reducing gas to accomplish this result.

By the aid of the microscope, Hebron, an associate of Carrie J. Everson, discovered that the desirable minerals, to be saved by concentration, have larger pores and surfaces than equal sized gangue particles. This gives greater chance for gas occlusion. Oil and like substances are usually but slightly soluble in water. The reverse is also true. There is little adhesion between water and a surface wetted with oil, or oil and a surface wetted with water. Oil, due to its property of capillary attraction, can readily enter the pores of solids not filled with water. Therefore, most metals, sulphides and the like containing occluded air, are capable of absorbing more oil due to their larger pores and surfaces. With sufficient oil thus attached, agglomeration or bulk oil flotation takes place.

By this process of elimination, the same conclusion is reached as that demonstrated by Mickle's experiments. Gas is the necessary element for surface tension, bulk oil and froth flotation methods and this must be occluded gas. Nascent gas and an electrolyte are also essential elements for froth flotation.

³U. S. Pat. No. 345,951. 1885.

Function of Electrolytes

What is the function of the electrolyte? As has been shown, an acid or an alkali creates the selective action in froth flotation. How? By its ability to vary the contact angle between the surface of the mineral particle and the liquid film on either a bubble of measurable radius or a horizontal liquid surface of infinite radius. Dr. Young showed the constancy of contact angles. H. Livingston Sulman, investigating figures for contact angles found "discrepant readings" due to "existence of a variable range of the contact angle." C. G. Lamb termed this angular difference "the angle of hysteresis." Speaking of this, Mr. Sulman says: "Whereas the angular hysteresis of silica in plain water may exceed 30 deg., thus indicating the substance to have a definite power to occlude gas and to float, it drops from 4 deg. to nil in water acidulated with sulphuric acid."

The occluded gas can be driven out from a solid in the same way that it can be driven from a liquid. This gas of the solid particles will cause them to become nuclei for the formation of bubbles from the gas "coming into being" from the liquid and, as the bubbles grow, the particles are lifted or floated. Since there is more occluded gas in the metallic particles, all that is necessary to create the selective action of flotation is to drive out a considerable portion of the occluded gas from all particles. There then will be insufficient gas remaining with the gangue particles to cause them to act as nuclei upon which to grow bubbles. The metallic particles still having occluded gas are then floated while the gangue particles sink.

As above shown, this selective effect is produced in extremely dilute solutions. An electrolyte produces it, but how? It was also shown that some force is required to expel occluded gas. No outside force such as pressure or heat is the cause. Therefore it is an internal one that drives this occluded gas from the mineral particles. The ions of the electrolyte displace the equilibrium and the force that causes the gas occlusion is, at least partially, neutralized so that the tendency of the gas is then to diffuse throughout the liquid instead of remaining in the solid.

Effect of Osmosis

A parallel case in physics is osmosis. The function of the electrolyte, therefore, is to create osmotic pressure. The septum is the surface of the mineral particle. Ions of the electrolyte enter the solid while those of the gas leave. This action continues to the eutectic point and bubbles form on the metallic particles, as described above. Greater delicacy of manipulation is obtained with an alkali. Further advancement along this line means that selective action can be created between sulphates, carbonates, etc., and gangue minerals. Also that, by means of a variation of the electrolyte, preferential flotation can be effected and different metals can be separated.

Increased strength of the electrolyte will sometimes "kill" the float; or, in other words, increased osmotic pressure drives the air from the metallic particles leaving them in the same condition as those of the gangue. This effect is not to be confused with an entirely different phenomenon which produces the same effect. Colloidal impurities like tannin, saponin, etc., or volatile oils and the like destroy bubbles by reducing the surface tension to the extent that the gas pressure from within bursts them. This weakening of the surface tension by a colloid is thus seen to be entirely different from the strengthening of osmotic pressure by a crystalline although the result is practically the same—no froth.

In studying this selective action, it is difficult to explain the motive power of osmosis, as present authorities do not agree. According to the Van't Hoff school it is the kinetic energy of the dissolved molecules obeying the laws governing gas pressure. It is the impact of these molecules against the walls of the semi-permeable membrane. On the other hand, Kahlenberg shows it to be the force of chemical affinity, while Professor Traube proves it is an "interfacial pressure obtained by subtracting the surface tension of one fluid from the tension of the fluid into which it diffuses." Since surface tension is a cohesive force, osmosis may depend upon electromotive force because, according to both Sir Oliver Lodge³ and Fernando Sanford,⁴ the forces of chemical affinity and cohesion are electrical. This is a much mooted question for, by assuming Dr. Lupke's⁵ "Osmotic Theory of the Current of Galvanic Cells," the starting point is again reached. Fortunately the question as to the motive power of osmosis has no bearing on the result of the selective action in flotation caused by osmosis. As shown, this selective action in all three methods of flotation depends primarily upon gas occlusion by the mineral to be floated. Mickle showed that no mineral will float on the surface of hot acid solution, even if dilute. Thus an electrolyte creates a greater selective action in surface tension flotation.

This selective tendency exists in neutral solutions due to the fact, that metallic particles occlude more gas than others. In bulk oil flotation, the metallic particles have occluded more air and, hence, are more easily wetted with oil than with water. The osmotic force set up by the electrolyte in froth flotation expels occluded gas from the mineral particles. There is still left with the metallic particles sufficient gas for them to act as nuclei so that the nascent gas of the liquid may form bubbles to float them.

Just as vapor must have a nucleus upon which to form a rain drop, so the nascent gas in flotation pulp must have a nucleus upon which to form a bubble. Duhem⁶ shows that a bubble will never form where the liquid is continuous, due to the fact that its infinitely small radius would be less than the limiting radius of collapsibility. Note how the vapor bubbles of boiling water form on the bottom or sides of the vessel.

Action of Bubbles

Not only are bubbles necessary for froth, but they must be more or less persistent. The surface film that encloses the bubble as it is formed in the interior of the liquid becomes a part of that bubble and, due to surface tension, remains with it throughout its passage to the surface of the liquid, in the same way that the surface film of a soap bubble remains with it throughout its passage in the air. This is easily proved by slowly blowing a colored bubble at the bottom of a large beaker of which the upper portion at least is filled with clear liquid. Due to this fact, the bubbles may have their films strengthened or toughened so they will endure for a longer time. Therefore, if the bubble be coated with some such substance as oil, the total force of surface tension is increased, due to the surface tension of the water film plus that of the oil film. Surface tension tends to decrease the size of the bubble as is well illustrated by Boys,⁷ while the expansive force of the gas enclosed tends to enlarge it. The hydrostatic head aids surface tension in maintaining the bubble in the interior of the liquid.

⁷Soap Bubbles, by C. V. Boys.

^{*}Presidential address of H. Livingston Sulman. Institution of Mining and Metallurgy Transactions, 1912.

Arriving at the surface, the bubble may burst due to: (1) interior gas expansion; (2) adhesive force of the contained gas for the atmosphere; (3) evaporation of the enclosing film. Therefore an immiscible substance aids in two ways in making the bubble more persistent: (1) adding to the force of surface tension; (2) forming a film less easily evaporated. Since molecular forces are dealt with, these films approach one molecule in thickness and hence little oil is required. The colors of the bubbles also show this.

In addition to the oil film, the bubbles may be still further strengthened by an armor of metallic particles. These metallic particles containing occluded gas are, as shown above, more easily oil-coated than gangue particles. Due to cohesion, an electrical force, these particles are firmly held together and to the bubble film, which is then enclosed in a network of them just as a balloon is enclosed in a netting of rope. Bubbles thus made will endure for days and have been spoken of as "oil froth."

Oils that are good "collectors" are practically insoluble in water and form a film not easily evaporated, so make persistent bubbles. Good "frothers" are oils more or less soluble and, while they make quantities of bubbles and much froth, evaporate quickly, so that the bubbles burst more readily. Mineral particles are very easily coated with volatile oils and the bubbles are readily armored, but they burst readily, sometimes with violence. Being soluble, these oils decrease the surface tension since their surface tension is less than that of water.

Most oils aid flotation in three ways: by (1) increasing surface tension of the oil film with the additional force of surface tension of the water film; (2) decreasing adhesive force of the water for metallic particles by forming films around them; and (3) increasing cohesive force of metallic particles for each other by means of the oil film. Thus it is seen that although oil is a great aid, there can be no universal theory for flotation which considers oil necessary. By this method of elimination, it is shown that all processes and kinds of flotation can be satisfactorily explained by gas occlusion and that the bubbles for froth formation are from nascent gas.

Imperial Reduction Co., Pasadena, Cal.

Coal, Coke and Limestone Efficiency in Blast Furnace Operation

BY BIRGER F. BURMAN

(Concluded from page 140)

Limestone Efficiency

Limestone is of a strong basic composition, while alumina must be considered as a distinct acid. Before limestone can act as a flux on other materials its own impurities must be satisfied by part of its own bases. Therefore the value of a limestone is dependent on the amount of its net available base.

A pure limestone contains 100 per cent carbonates, representing the maximum amount any limestone can contain. Consequently such a limestone must be considered as "100 per cent efficient" and another limestone with less carbonates as less efficient.

Phosphorus, except in very small quantities, must not be present; therefore, a limestone, even very efficient otherwise but containing comparatively much phosphorus, must be eliminated at the quarry.

Sulphur, on the other hand, may be taken care of by the furnace slag. However, it increases the cost of production. Therefore it should come within the scope of the regulating guide of an efficiency system. Under ordinary conditions the quantity of slag in the furnace

is more than sufficient to keep this sulphur in a safe solution, but when it is remembered that its presence increases the already too high amount in the coke, it is evident that it will be of advantage to keep the amount of sulphur in limestone at its minimum.

The actual weights and not the oxygen shall determine the value of each part, whether base or acid in the matter of fluxing; and for the sake of further simplicity Al_2O_3 shall be considered equal to SiO_2 as acid and MgO equal to CaO as base. Other bases present as, for instance, FeO , shall ordinarily not be included with CaO and MgO when determining the efficiency, neither shall sulphur as CaS . In other words, in order to make as little work as possible for the chemist, analyses on SiO_2 and Al_2O_3 only shall be made on every limestone shipment at the quarry and on the daily consumption at the blast furnace. The difference between 100 and the summated acid, thus found, shall be considered as summated carbonate. For instance, a limestone containing

SiO_2	6.72 per cent
Al_2O_3	4.07 per cent

Total 10.79 per cent summated acid

will therefore have $100 - 10.79 = 89.21$ per cent summated carbonate. If the slag runs with summated acid equal to summated base, the weight of useless stone must be 2 (summated acid) plus the weight of that carbonic oxide, which accompanies the base of the same weight as the summated acid. In this case the useless part of the limestone, considering CaO , CO , as flux, will therefore be $10.79 + (1.79 \times 10.79) = 30.10$ per cent, and the efficiency about 69.90 per cent.

Above calculations will be close enough for everyday use in order to simplify work in the laboratory. However, at the end of the week a complete analysis is made of an average sample of all the limestone consumed during the week. Based on this analysis a more thorough record is made. FeO as base is now included in the summated base and P_2O_5 and CaS are given due consideration.

LIMESTONE AT THE QUARRY

It is, of course, at the quarry that the quality of the limestone must be kept up or improved upon by the elimination of impurities. This can be done only by the aid of the laboratory. Analyses are made on average samples, taken on every shipment, sent to the blast furnace, and with the shipment the following report is forwarded:

REPORT ON LIMESTONE SHIPMENT NO.

Date of shipment:		
Number of cars:		
Weight of limestone (in tons of 2240 pounds):		tons.
Kind of limestone:		
Analysis: SiO_2	7.70%	
Al_2O_3	4.58%	12.28%
P		.01%
S		15%
Stone efficiency: $100 - [12.28 + (1.79 \times 12.28)] = 65.74\%$		

LIMESTONE AT THE BLAST FURNACE

There might be established such conditions at the quarry and the blast furnace that resampling and check analyzing would be unnecessary. However, that would be exceptional. It is safe to say that all limestone used at the blast furnace must be sampled and analyzed daily.

METHODS OF TAKING AVERAGE SAMPLE

All limestone used each day is sampled as usual. A certain weight of this sample, crushed and prepared, is put aside. The amount is a fixed weight per 1000 lb. of limestone used. At the end of the week the seven samples thus received are thoroughly mixed.

METHODS OF REPORTING ANALYSES

Daily form:

DAILY ANALYSIS NO. OF LIMESTONE

Used in the blast furnace No.	Date:	Tons
Weight (in tons of 2240 pounds):		
Kind of limestone:		
SiO ₂ %		
Al ₂ O ₃ %		
P %		
S %		

Weekly form:

AVERAGE ANALYSIS NO. OF LIMESTONE

Used in the blast furnace No.	during the week ending:
Daily samples used: No.	thoroughly mixed:
Weight (in tons of 2240 pounds):	Tons.
Kind of limestone:	
SiO ₂ 5.80 %	Summated acid = 9.80%
Al ₂ O ₃ 4.00 %	
CaO 46.54 %	
MgO 2.78 %	Summated base = 50.21%
FeO .89 %	Fe .69%
P ₂ O ₅ .023% P .01%	
CaS .340% S .15%	
CO ₂ 36.57 %	in combination CaO, CO ₂
CO ₂ 3.06 %	in combination, MgO, CO ₂
Total 100.003%	

NOTE:

P ₂ O ₅	equals 2.29 x P
CaS	equals 2.25 x S
CaO	from which Ca in CaS has been reduced equals 1.75 x S
CO ₂	equals 11 x CaO
CO ₂	14
	equals 1.1 MgO

RELATIVE VALUE OF LIMESTONE

As was said under coke regarding the necessity of figuring out the relative value of that material, this can also be said of limestone. Standards are necessary for comparison, and averages for some previous period, say one year, should be adopted. Figures given below are merely inserted as examples and should be modified to suit local conditions.

STANDARDS:

1. Cost of coke per ton of 2000 pounds, here assumed to be \$2.20
2. * Cost of pure available carbon (sulphur included), here assumed to be 4.701
3. Cost of limestone per ton of 2240 pounds, here assumed to be 1.10
4. Cost of slag from tapping to its disposal by the R. R., per ton of 2240 pounds, here assumed to be 0.20
5. Amount of pure fixed carbon to melt the slag = 0.22S pound per pound of slag.
6. Acids in the slag. Here assumed to be 1.
7. Actual weights and not oxygen proportions shall be considered as finding standards.
8. Al₂O₃ shall be considered as acid.
9. CaS shall be considered as neutral.
10. Analyses of coke and coke ash—here assumed (see below).
11. Maximum amount of sulphur in the slag—here assumed to be 1.40%.
12. The relative value of any limestone shall be determined by the cost per ton of 2240 pounds of pure available base.
13. It is assumed that coke ash and slag from flux go unchanged into the furnace slag.

EXAMPLE:

A certain limestone gives the following analysis:

SiO ₂ 5.80%	} 9.80% acids
Al ₂ O ₃ 4.00%	
CaO 46.54%	} 50.21% bases
MgO 2.78%	
FeO .89%	
P ₂ O ₅ .023%	P .01%
CaS .340%	S .15%
CO ₂ 39.63%	

Total 100.003%

*This is a matter of course.—See Coke Efficiency.
Going to the slag: $9.80 + 50.21 + 0.34 = 60.35$

Standard analysis of coke (wet) used:

Moisture	2.50 %	SiO ₂ 6.02 %
Vol. matter	1.50 %	Al ₂ O ₃ 3.61 %
Fixed carbon	82.52 %	CaO .666 %
Ash	12.53 %	MgO .24 %
P (remaining in the ash)	.024%	FeO 1.80 %
S (remaining in the ash)	.130%	P ₂ O ₅ .033%
S (remaining in the combustible)	.750%	CaS .293%
		Total 12.684%

Going to the slag: $12.684 - 0.055 = 12.629$

Limestone: SiO ₂ 5.80 %	Going to the slag: 5.80
Al ₂ O ₃ 4.00 %	4.00
CaO 46.54 %	46.54
MgO 2.78 %	2.78
FeO .89 %	.89
P ₂ O ₅ .023% P .01%	.34 CaS
CaS .340% S .15%	Total slag 60.35
CO ₂ 39.63 %	Bases in excess 50.21 - 9.80
Total 100.003%	Slag from impurities 60.35 - 40.41 = 19.94

Sulphur dissolving efficiency of the slag:

Slag required to keep 0.15% S in solution:

$$\frac{1.40}{100} = 0.15$$

and $y = 10.714$ parts of slag per 100 parts of limestone.

Net slag available 60.35 - 10.714 = 49.636
 Sulphur dissolving efficiency $49.636 \times 100 \div 60.35 = 82.25 \%$
 Slag efficiency = Total slag (see above) 60.35 %
 Fluxing efficiency = Bases in excess (see above) 40.41 %
 Fuel required per 100 parts of limestone:

Sulphur in coke: $0.05883 \times 0.88 = 0.05177$
 Sulphur in stone: 0.15 0.20177 S

Slag must be supplied for this sulphur.

See Coke and Limestone—Supplement—Cases II and III.

5.883 coke requires $0.05883 \times 6.924 = 0.407$ base and produces 0.05883 $\times 19.553 = 1.150$ slag
 The 0.20177 sulphur requires $0.20177 \times 24.16 = 4.875$ coke
 The 0.20177 sulphur requires $0.20177 \times 1.43 = 0.289$ base
 The 0.20177 sulphur requires $0.20177 \times 81.89 = 16.523$ slag
 The 0.20177 sulphur produces $0.20177 \times 86.61 = 17.475$ slag
 Difference between slag produced and slag required: 0.952 slag
 Total coke required 5.883 + 4.875 = 10.758 coke
 Total slag present $19.94 + 1.15 = 0.952 = 22.042$ slag
 Sulphur-free slag available 22.042 - 16.523 = 5.519 slag
 Base available $40.41 - (0.407 + 0.289) = 39.714$ slag
 Sulphur in coke 0.10758 $\times 0.88 = 0.09467$
 Sulphur in stone 0.15 0.24467 S
 Sulphur in slag $24.467 + 17.475 = 1.40\%$

One part of limestone:

requires 0.10758 parts of coke
 furnishes 0.05519 parts of sulphur-free slag
 furnishes 0.39714 parts of net available bases
 furnishes 0.22042 parts of sulphur saturated slag

COST—SULPHUR INCLUDED:

Limestone costs \$1.10 $\times 1. = 0.39714 = \$2.7698$
 Coke costs $2.20 \times 1.12 \times 0.10758 \div 0.39714 = .6675$
 Slag costs $0.20 \times 0.22042 \div 0.39714 = .1110$

Total \$3.5483

Deduct for sulphur-free slag—See Coke and Limestone—Supplement, Case I.

$80.001 \times 2240 \times 0.05519 \div 0.39714 = 80.3113$
 Net cost per ton of 2240 pounds of net available base = 3.237

Net cost per ton of 2240 pounds of limestone:

$$3.2193 \div (1 + 0.39714) = 1.279$$

COST—SULPHUR NOT INCLUDED:

One part of limestone

requires 0.05883 parts of coke
 furnishes 0.4041 - 0.00407 = 0.40 parts of net available base
 furnishes 0.1994 + 0.0115 = 0.2109 parts of slag
 Limestone costs $1.10 \times 1. = 0.40 = \2.750
 Coke costs $2.20 \times 1.12 \times 0.05883 \div 0.40 = .362$
 Slag costs $0.20 \times 0.2109 \div 0.40 = .101$

Total cost per ton of 2240 pounds of net available base \$3.123
 Total cost per ton of 2240 pounds of limestone $123 \div (1 + 0.40) = \$1.249$
 Cost due to sulphur alone, per ton of 2240 pounds of limestone (no cost for reduction included) $1.279 - 1.249 = \$0.030$

COKE AND LIMESTONE—SUPPLEMENT

As sulphur plays such an important part in the blast furnace operations, where its presence in the slag must not exceed a certain limit, more or less dependent on local conditions, great care must, of course, be taken to produce sufficient quantities of the slag, in order to keep the sulphur on hand in a safe solution. While sulphur is transferred into the blast furnace through the medium of most anything that is charged into it, it is principally coke, however, that is the source of this element. If it were not for the coke, hardly any precautions would be needed, as the slag, that would have to be made anyway, usually is more than sufficient to take care of the smaller amount present in ore and flux. For calculating the relative cost of any kind of material entering the blast furnace it will therefore be convenient to have standard figures on hand relative to the amount of coke, flux, etc., necessary to put a unit of sulphur into the slag, thereby producing a standard sulphur solution. The sulphur in question will, of course, be the surplus amount left over after the slag on hand has been satisfied.

Calculations given below are examples and must be modified to suit local conditions. Results are, however, standards and should be made up once for all to be used during a period of say one year or during the time the standard analyses of coke and limestone are in force. A standard sulphur solution must also be adopted. There will now be five different cases to consider:

Case I. Limestone, sand, or its equivalence, and coke added.

II. Net base, sand or its equivalence, and coke added.

III. Net sulphur-free slag, net base for coke ash and coke added.

IV. Net sulphur-free slag, limestone for coke ash and coke added.

V. Limestone, sand or its equivalents, and fixed carbon added.

In examples, given below, our standard analyses of coke and limestone (see under these items) have been utilized; also a sulphur solution of 1.40% S.

CASE I

LIMESTONE, SAND OR ITS EQUIVALENCE, AND COKE ADDED:

Sulphur in slag from limestone and sand or its equivalence $\frac{3.943}{100} \times \frac{100}{100} = 3.943\%$
 Sulphur in slag from coke $\frac{1.40}{100} \times \frac{100}{100} = 1.40\%$
 Sulphur in the final slag $\frac{100}{100} = 100\%$

Slag required to keep one part of sulphur in $\times\%$ solution = $\frac{100}{\times} = 81.433$

Slag shall have acids=bases.
 Acids must be brought in from other sources than the limestone; this may be sand or its equivalence.
 Slag from sand or its equivalence $= y = \frac{100}{\times} - y$

Slag from limestone is of 82.25% sulphur dissolving efficiency.
 $\therefore$ Slag from limestone $= \left(\frac{100}{\times} - y \right) \div 0.8225$

Limestone is 60.35% slag efficient.

$\therefore$ Limestone $= \left(\frac{100}{\times} - y \right) \div 0.8225 \div 0.6035$

Bases $= 0.4041 \left(\frac{100}{\times} - y \right) \div 0.8225 \div 0.6035$

But acids=bases.
 $\therefore y = 0.4041 \left(\frac{100}{\times} - y \right) \div 0.8225 \div 0.6035$

and sand or bases $= y = \frac{40.41}{0.9x} = 38.543$

Limestone required $= \left(\frac{40.41}{0.9x} \right) \div 0.4041 = \frac{100}{0.9x}$

Slag from limestone $= 0.6035 \left(\frac{100}{0.9x} \right)$

Total slag $= \frac{40.41}{0.9x} + \frac{60.35}{0.9x} = \frac{100.76}{0.9x}$

Carbon to melt this slag $= 0.228 \left(\frac{100.76}{0.9x} \right)$

Coke is 77.28% carbon efficient.

$\therefore$ Coke $= 0.228 \left(\frac{100.76}{0.9x} \right) \div 0.7728$

Slag from coke $= 0.2297 \left[0.228 \left(\frac{100.76}{0.9x} \right) \div 0.7728 \right]$

$\therefore \frac{100.76x}{100(0.9x)} + \frac{3.943}{100} \left\{ 0.2297 \left[0.228 \left(\frac{100.76}{0.9x} \right) \div 0.7728 \right] \right\}$

$= \frac{1.40}{100} + \frac{100.76}{100(0.9x)} + 0.2297 \left[0.228 \left(\frac{100.76}{0.9x} \right) \div 0.7728 \right]$
 and $x = 1.228\%$

One part of sulphur requires therefore:

limestone to flux coke $0.1713 \times 26.882 = 4.605$
 limestone for one part sulphur $= 93.433$ 95.038 stone

containing 35.400 base
 sand or its equivalence 36.543 sand
 coke 26.882 coke
 slag produced: From sand or its equivalence 36.545
 From stone 54.576
 From coke 6.175 97.296 slag

Sulphur in stone $95.038 \times 0.0015 = .14256$
 Sulphur in coke $26.882 \times 0.0088 = .23656$
 Sulphur in base for these calculations 1 1.37912 S

Sulphur in slag (per cent) $137.912 \div 97.296 = 1.417\%$

The cost of slagging one pound of sulphur will be:

for coke $\$2.20 \div 2000 \times 26.882 = \0.0295
 for stone $1.10 \div 2240 \times 95.038 = .0467$
 for sand or its equivalence $1.10 \div 2240 \times 36.515 = .0108$
 for slag $0.20 \div 2240 \times 97.296 = .0087$ \$0.0957

The value of one pound of sulphur-free slag will be: $0.0957 \div 97.296 = \$0.001$

CASE II

NET BASE, SAND OR ITS EQUIVALENCE AND COKE ADDED:

100 parts of coke require of net bases $9.63 - 2.706 = 6.924$
 100 parts of coke furnish of slag $12.629 + 6.924 = 19.553$
 Net bases added in per cent of total slag 35.41%
 Sulphur in slag $88 + 19.553 = 1.30\%$

Using these figures in formula of Case I we get:

$x = 1.2212\%$
 Slag $= \frac{100}{1.2212} = 81.89$

per one part of sulphur:

Coke $0.228 \times 81.89 \div 0.7728 = 24.16$
 Slag from coke plus bases added $24.16 \times 0.19553 = 4.72$
 Total slag $81.89 + 4.72 = 86.61$
 Bases in coke slag added $4.72 \times 0.3541 = 1.67$

Added thus:

Coke 24.160
 Base $(81.89 \div 2) + 1.67 = 42.615$
 Sand or its equivalence $81.89 \div 2 = 40.945$
 Slag produced 86.610

Sulphur in coke $0.2416 \times 0.88 = 0.2126$
 Sulphur in base for these calculations 1 1.2126 S
 Sulphur in slag (per cent) $121.26 \div 86.61 = 1.40\%$

CASE III

NET SULPHUR-FREE SLAG, NET BASE FOR COKE ASH AND COKE ADDED:

This is the same as Case II, with the following modifications added:
 Coke 24.160
 Base 1.697
 Slag—half acids, half bases 81.810
 Slag produced 86.600

CASE IV

NET SULPHUR-FREE SLAG, LIMESTONE FOR COKE ASH AND COKE ADDED:

In this case figures for coke as shown in Case I must be used
 $x = 100 \cdot 3.943 \left\{ 0.2297 \left[0.228 \left(\frac{100}{x} \right) \div 0.7728 \right] \right\} = \frac{1.40}{100} + \frac{100}{100} \left\{ 0.2297 \left[0.228 \left(\frac{100}{x} \right) \div 0.7728 \right] \right\}$
 and $x = 1.2277$
 slag $= 100 \div 1.2277 = 81.45$

per one part of sulphur:
 Coke $(0.228 \times 81.45) \div 0.7728 = 24.03$
 Slag from coke plus that from stone to flux ash $24.03 \times 0.2297 = 5.52$
 Total slag $81.45 + 5.52 = 86.97$

Added thus:
 Coke 24.03
 Stone for coke ash $24.03 \times 0.1713 = 4.12$
 Slag—half acids, half bases 81.45
 Slag produced 86.97

Sulphur in coke $0.2403 \times 0.88 = 0.21146$
 Sulphur in stone $0.0412 \times 0.15 = 0.00618$
 Sulphur for base for these calculations 1 1.2176 S

Sulphur in slag (per cent) $121.76 \div 86.97 = 1.40\%$

CASE V

LIMESTONE, SAND OR ITS EQUIVALENCE, AND FIXED CARBON ADDED:

Use formula in Case I, eliminating coke and substituting 1.40% for x .
 $\therefore$ Slag $= \frac{100}{1.40} = 71.42$
 $y = 0.4041 \left(\frac{71.43}{0.8225} - y \right) \div 0.6035$

Sand or base $= y = \frac{32.07}{0.9x} = 32.07$
 Stone $79.36 \div 0.4041 = 79.36$
 Slag in stone $79.36 \times 0.6035 = 47.89$
 Total slag $32.07 + 47.89 = 79.96$

Added thus per one part of sulphur.
 Fixed carbon $79.96 \times 0.228 = 18.23$
 Stone 79.36
 Sand or its equivalence 32.07
 Slag produced 79.96

Sulphur in stone $0.7936 \times 0.15 = 0.119$
 Sulphur in base for these calculations 1 1.119 S

Sulphur in slag (per cent) $111.90 \div 79.96 = 1.40\%$

Electrochemical War Supplies

A Report of the Papers Presented at the Meeting of the New York Section of the American Electrochemical Society on February 11

Such a varied and attractive program of papers on "electrochemical war supplies" had been arranged for the meeting of the New York Section of the American Electrochemical Society on February 11, 1916, that the attendance broke all records. Not even standing room was left, and for the first time in the history of the Chemists' Club it became necessary to close the outside doors in order to keep within the police regulations as to the capacity of the hall.

Dr. Colin G. Fink, chairman of the New York section of the American Electrochemical Society, in opening the meeting said that it had been arranged to bring before the public a few of the remarkable achievements of American electrochemistry. "Owing to the fact that the dyeing industry of this country was not comparable to that of Germany, the American chemist has been branded as incompetent. The people as a whole are sadly ignorant of the wonderful accomplishments of the American electrochemists; they do not know and have never realized that the electrochemical industry of the United States is the very foremost of the world. Furthermore, the electrochemistry is a very important factor in national preparedness."

The Problem of Preparedness

Mr. W. L. Saunders, Chairman of the Board of the Ingersoll-Rand Co., President of the American Institute of Mining Engineers, and Vice Chairman of the Naval Consulting Board, was the first speaker. It is hardly necessary to say that he spoke very well. By some funny stories cleverly told—one of them how he once got a prize in chemical experimental work in his student days—he got his audience quickly into the best of humor and then launched into a discussion of preparedness.

The subject of preparedness is one in which I am very much interested. I cannot find myself getting into enthusiasm on the subject as to whether or not we should have an army of four hundred men or a million men; whether it should be a Continental Army or a State Militia, whether we should have instruction compulsory or instruction in the schools. I cannot get myself enthusiastic on the subject as to whether we shall have thirty-three dreadnaughts, forty-three or twenty-three, or whether we shall have a certain number of torpedo boats in proportion to a certain number of fast cruisers. All that, it seems to me, is a question of evolution. We are new in this question of preparedness. We are new as a war-like people. We do not know anything about it, and we had better reach a conclusion on the subject through deliberation and by a gradual process. But there is one thing that it seems to me that we do know—and if we do not we ought to know it—and there is one line of action in which we ought to begin at once, and that is, we should *begin at the bottom and prepare our industries.*

The first consideration is the industrial consideration of the country. Mines and mills and works and factories we have in large abundance. But they are all separated and disassociated, there is no relation between one and the other, there is no relation between any of the industries of the United States or the mines of the United States and the Government at Washington. You hear of a good many large concerns making large amounts of ammunition and making a good deal of money out of it. It is a new business, and it is attractive to them financially, but they know nothing about the relation of the United States to ammunition. They know nothing about what kind of shrapnel or shells the United States would require in case we were in trouble. In other words, the first question and the most im-

portant consideration in talking about preparedness against attack, is to have the industries of this country not only acquainted with each other and co-related, but in touch with the Government of the United States, so that the Government of the United States might tell them exactly what might be expected of them in case we ever get in trouble. No such thing has ever been done in this country. We know nothing about it, yet what little experience some of us have had on the Naval Consulting Board, we are inclined to believe that when the inventory is taken of the condition of the United States, the strength of the United States for peace or war will be found to be absolutely amazing. We do not know what we have got here in this country.

The Steel Corporation directors and officers know what they have got in the shops of the Corporation, and other concerns may be well acquainted with what the conditions are of their work, but we do not know the enormous volume and strength of the industries of the United States which might, if co-related and mobilized, put this country into an impregnable position against attack.

It seems to me, ladies and gentlemen, that it is far more important in the interests of peace and safety, for the United States to train its men in the works and have them organized so that they know what to do and do it efficiently, than it is to get them out in the trenches, or over at Plattsburgh, or out on the seas, getting trained to shoot guns, because if we got the organization in the works, and if we got the maximum resources in this country in iron and steel and coal and copper, we can get the men and we can train the men in a very short time to know how to handle those munitions and to oppose the strongest foe that the world can bring against us.

Mr. Saunders pointed out that the yearly coal consumption per capita indicates the industrial prosperity of a nation. This is five tons for the United States, four tons for Germany, four tons for England, 1.6 tons for France, 0.25 tons for Russia.¹

Anybody who has been in Russia as I have travelled over it several times, can see that the people of Russia, while they are intelligent, good people, yet they are not industrially prosperous. In other words, the individual in Russia can only produce what he can do with his hands. He will go out into the field and hoe and raise potatoes and cabbage. If he is working in the shops, he is working in some small establishment where his productivity is very limited. The same individual in the United States may produce ten to twenty times as much, because his work is done in factories on a large scale, where the productivity of the individual is multiplied five, ten and twenty times.

I have gone rather at length into this subject only to make plain the first point that is in my mind, and that is that industrially in times of peace, we are the strongest nation in the world. The three foremost industrial nations that I spoke of, the United States, Germany and England, produce and consume ninety per cent of the iron ore in the world. That is another indication of industrial prosperity.

Now, what is the difference between the United States and Germany, for instance? We have our industrial prosperity almost perfected on lines of peace. I venture to say that if the United States Steel Corporation or the Harvester Corporation or the Standard Oil Company, or any other of these large concerns which are run so well, so economically and so efficiently, were lifted bodily from this country and planted in either England or Germany, they would not be run any better. If they were lifted bodily and planted in Russia, they would fail, they would not be a success. I do not believe France could run them. Certainly Spain could not, nor Italy, and to take an exaggerated illustration, suppose they were lifted into China, can you imagine a great industry like the Steel Corporation run efficiently and profitably in China? No, it is impossible. In Japan they could not be run profitably. I have been in Japan and I have watched and studied the Imperial Steel Works with the

¹Compare the paper by J. R. Finlay, this journal, Sept. 1, 1915, vol. XIII, p. 647.

Government's money behind it, and yet they do not know how to produce steel rails as cheap as we do in the United States. They have not yet the efficient step that we have got in this country. Now Germany has got it, and Germany has got it not only for peace, but she has got it for war. But we have not got it for war, and it will take a long period of years to get it for war. I doubt whether our industries can be efficiently organized on a war basis in a period of even ten years, but we had better begin now. We do not control the world, we are only a small part of it, and a large part of it is in a conflagration at the present time. We had better prepare and protect ourselves and see that our house is in order, and we ought to begin at the bottom, and the bottom is in the industries of the United States.

And as a foundation we have the chemical industries of the United States, because chemistry is at the bottom of all our industry. We discover through chemistry. Chemistry is the basis of all our industrial prosperity, not only in mining and metallurgy, but in the arts in general. My whole experience in life has been a part of chemistry. I have been in business as an engineer, and week after week, in general work that I have done in connection with large corporations and in the management of work, have I found chemistry of advantage. Always questions come up wherein chemistry cuts an important figure—even in the question of drill steel, and why drill steel breaks under the hammer, and so, ladies and gentlemen, in conclusion I want to tell you that in industrial life, in both peace and war, the chemist is of the greatest importance.

Mr. Lawrence Addicks, president of the American Electrochemical Society, was unable to be present on account of illness, but had sent a letter in which he called attention to the fact that the war in Europe has accomplished two very important steps toward the military preparedness of this country. It has given a great many manufacturing concerns experience in adopting ordinary machinery to the special uses of turning out arms and ammunition, and it has sufficiently disturbed our imports to emphasize what would be our weak spots in self support in time of isolation. Aside from the broader view that nearly all production or manufacture contributes to war supplies, electrochemistry plays an important part in the production of some indispensable items—copper, aluminum, electrolytic zinc, various gases such as hydrogen, oxygen, chlorine, and acetylene, and finally the fixation of atmospheric nitrogen. Submarines could not be operated without the storage batteries and we must include wireless telephony. It may be included if the chemist and the electrical engineer put their heads together and do a little team work.

Fixation of Atmospheric Nitrogen

Mr. W. S. Landis, chief technologist of the American Cyanamid Company, said there was a widespread idea that Germany had been well prepared for the present war, as it had had large plants for atmospheric nitrogen fixation which could be diverted from fertilizer manufacture to munition manufacture, and that the development of an atmospheric nitrogen fixation industry requires years of work.

As a matter of record Germany at the outbreak of the European war possessed three cyanamid factories with a combined capacity of but little over 50,000 tons of cyanamid per year. There were then no arc processes at work in the country, and the Haber process was producing a comparatively small quantity of sulphate of ammonia.

In contrast with this Germany has to-day a production on an annual basis of almost 500,000 tons of cyanamid, and nearly 10,000 tons of arc-process nitric acid, all of which has been built and set into operation within eighteen months. Even the Haber process has been considerably increased in capacity, though the plant at Oppau suffered greatly, though indirectly, from an aeroplane visit. The present German investment in these atmospheric fixation processes is now over \$100,000,000, and Germany is enabled to meet not only its agricultural requirements for nitrogen, but its munition demands as well. In other words, Germany is now fixing atmospheric nitrogen in quantity such as to replace the entire importation of nitrogenous materials amounting annually to approximately 850,000 tons of nitrate of soda

and 40,000 tons of nitrate of lime, plus an indefinite amount of Norwegian cyanamid amounting probably to 20,000 tons annually. The munition plants are consuming nitric acid at a rate of 250,000 to 300,000 tons per year in addition to the above agricultural and manufacturing requirements.

Germany at the outbreak of the European war had no commercial plants oxidizing ammonia, though the processes now in use were then fairly well developed. It was not until after the beginning of the war that these processes were put to work on a large scale, and the tremendous amount of nitric acid required to maintain her powder supply is now almost exclusively obtained from these oxidation processes.

These figures are certainly impressive, illustrating what eighteen months can do toward meeting an emergency if the necessary funds are forthcoming and an intelligent organization directs their expenditure. We can well appreciate that this great feat was accomplished only by terrific strain upon the technical staff which had charge of the work, and undoubtedly at an extravagant cost.

The manufacture of cyanamid on this side of the Atlantic is conducted in Canada under American direction. It is carried on at a higher efficiency than in the German plants and a higher-grade product is made. Our transformation into ammonia is at an equal efficiency to theirs, and the operation is conducted with less men and with a simpler form of apparatus.

We further have in this country intimate knowledge of the design and experience in the operation of the successful ammonia oxidation process, and it will only be a matter of a short time now when a fair-sized plant will be producing nitric acid from cyanamid by this process in the United States. There are no problems concerned therewith, the solution of which is not now resident in the United States, and, therefore, we feel that this country is to-day in as good, if not in a better position to supply its own nitric acid for munition purposes than Germany was at the beginning of the war in July, 1914.

Hydrogen for Military Purposes

Capt. E. D. Ardery of the United States Army was the next speaker. He gave an outline of the various properties and general uses of hydrogen gas and then took up its applications for military purposes where it is used mostly for inflating balloons and also (in combination with oxygen gas) for welding and cutting. The lifting capacity of hydrogen gas is different, depending on the process of manufacture used; it usually ranges between 1.175 and 1.195 kg. per cubic meter.

Captain Ardery outlined the various methods for making hydrogen, of which there are many. The old method using iron filings or zinc with dilute sulphuric acid, the aluminium and caustic soda process used in the Russo-Japanese war, the silicon or ferrosilicon and caustic soda process and the method using a powdered mixture of ferrosilicon and sodium calcium oxide used by the French were mentioned. The calcium hydride or hydrolytic process, utilizing the reaction between calcium hydride and water, has also found some use abroad, the chief objection to it being its high cost. Hydron is a substance made in this country, which in contact with water generates hydrogen. The process of passing steam over red hot iron has also found application as has the coke and oil process. (For further information on these processes see this journal, Vol. IX, page 157, and Vol. XIII, page 567.)

The United States Signal Corps has made experiments on the refrigeration of illuminating gas for producing hydrogen and at Port Omaha, Neb., the army installed a plant for the generation of hydrogen by the electrolysis of water.

The chief objection in military work to utilizing the hydrogen set free from the electrolysis of water or salt solutions is the problem of compressing and transporting this gas. Portable plants are necessary to follow the army. Various portable plants are in use of various sizes. Hydrolith or calcium hydride and hydron are portable, as are also the installations

of several of the other processes. The Germans have achieved much success in transporting hydrogen gas in cylinders under pressure and also in pipe lines. It is claimed that in Germany large balloons are filled in 20 min. from hydrogen compressed in cylinders.

Niagara the Commercial Research Laboratory of the Nation

Mr. Albert H. Hooker, works manager of the Hooker Electrochemical Co., of Niagara Falls, N. Y., was the next speaker. He said that while the title, "New War Products," had been assigned to him for his paper, it hardly fitted the topic he had in mind. "However, it will do as well as any other to wander from."

One evening at Niagara Falls it was my fortune to sit next to an attorney (Mr. Scovele), who told me that some years ago he had been commissioned to visit London and place with a group of financiers an early issue of bonds of the Ontario Power Company. He was asked by these financiers what use his principals proposed to make of this development of about one hundred thousand horsepower. His reply to their question impressed me, for he stated that "when the Niagara Falls Power Company started their tunnel (about 1891), not one of the companies now using that power was in existence, and not only that but not one of the products now made by those companies, through the use of that power, was then known to commerce."

This statement, sweeping as it sounds, is nearly true, for aluminium, carborundum, alundum, silicon, artificial graphite, calcium carbide, cyanamide, ferrosilicon, ferrochromium, ferromanganese, along with electrolytically produced caustic soda, sodium, chlorine, chlorates, chloroform, carbon tetrachloride, etc., are all commercial products of the last twenty-five years, most of them having been developed through the impetus given by this Niagara Falls power development. The few that were made earlier were little more than chemical curiosities.

Cannot these be rightly spoken of as "new war products"? Certainly they played no part in the munitions, armament and equipment of our Civil War nor the War of 1870. But in what a sorry plight would any manufacturing country be to-day, and particularly either side of the present warring nations, without these materials!

Carborundum, alundum, aloxite, crysotol are all artificial abrasives used in modern grinding machinery for the manufacture of automobiles, guns, shells, shoes, armor plate and for the grinding of tools. There is hardly an industry where the tremendous decrease in production and increase in cost would not be felt were we without these artificial abrasives produced by the electric furnace at Niagara. Ferrosilicon, ferromanganese, ferrochromium, ferrotitanium, ferrotungsten and ferromolybdenum are all products which have become necessities in the steel furnaces of to-day, to the point where possibly 75 per cent of the steel production of the United States is dependent upon the products from the electric furnaces of Niagara Falls. What would we do in the way of modern open-hearth steel without ferrosilicon, or armor plate without ferrochromium, to say nothing of high-speed tool steels and all they mean for modern machinery manufacture, whether these machines are sewing machines, automobiles, agricultural machinery, steam engines, pumps, cannon or shells? England's embargo on ferroalloys would have crippled the industries of this country in a far more serious manner than the loss of all the German dyers, had not one of the companies at Niagara been able to divert a large block of power from the production of calcium carbide to the production of ferrochromium, ferrosilicon, etc. And still this would not have been possible were not the electrochemists, engineers and operatives already at hand and skilled in the art; and further this might not have been possible without additional power development had we needed at the same time, as Germany does to-day, every last ounce of carbide for the fixation of nitrogen.

Caustic soda is all important in the manufacture of soap, for the refining of oils, the mercerizing of cotton to produce artificial silk, and a hundred familiar uses, yet it takes on additional importance to-day when we think of caustic melts in the production of dyes, the manufacture of picric acid and other nitro explosives. Sodium we seldom see, and are likely to connect this substance with a few lecture experiments, yet metallic sodium made at Niagara Falls forms the basis for all of the cyanide in which so many of our mines depend for the recovery of the precious metals. When the German supply of cyanide was cut off, it looked for a time as if many mines would have to close. Here

again an increase in production made possible a restored balance, and fortunately a little power was available for the purpose.

Upon bleaching powder, liquid chlorine and hydrochlorites we depend for the bleaching of our cotton cloth, the bleaching of wood fiber for the production of book paper, the sterilization of water supplies of many of our cities thus preventing typhoid fever, dysentery and other diseases. The electrolytic plants at Niagara Falls form the center of this important industry. They, as well as all other electrolytic plants in the country, are dependent upon Acheson graphite made at Niagara Falls for their graphite electrodes. These chlorine products have all taken on a new interest, liquid chlorine as a means of offense and defense, chlorinated benzol, etc., as necessary intermediates for the production of dyes and explosives. Are these new plants and the knowledge and skill required to operate them—experience obtained at tremendous cost—to be scrapped and lost after the present crisis is over? Or, are we to continue the operation along the line of peaceful, constructive manufacturing, increasing our skill and knowledge and retaining a skilled force of workers, chemists, engineers and operatives? Much will depend on the policy of our Government.

Is not Germany, with her supply of Chilean saltpeter, cut off, absolutely dependent upon the fixation of nitrogen by the electric furnace, the electric arc or the use of electrolytic hydrogen for all of her nitro explosives? Were it not for her foresight in considering this eventuality and subsidizing the development of the nitrate industry in Norway with its cheap water power, and then carrying the development work to a point where in an emergency like the present even power produced from coal could for the time supply her needs for nitric acid from internal sources, how otherwise could she stand to-day with England's fleet in command of the means of communication with the Chilean saltpeter deposits?

A NEW PROPOSAL OF NIAGARA FALLS POWER DEVELOPMENT

What are we doing to-day to supply our needs in a like emergency? I have a remedy to propose, and one which I feel it a duty to urge, for your earnest consideration.

As this was written, I saw from my window the waters of the Niagara River flowing by with a capability of being developed into perhaps five million horsepower—the most uniform and constant water power in the world. I am very fond of the impressive beauty of its mighty falls and the wonderful gorge and rapids below, and only as a last resort in the event of a national defense necessity would I do anything to injure that landscape. Such injury, however, is not necessary. As I study the daily moods of the falls, I see the ebb and flow of water due to the direction and velocity of the wind on Lake Erie, making far greater difference in the volume of water passing over the brink of the Falls than is caused by the present diversion of water producing some five hundred thousand horsepower. I also see that the beauty of the falls is not at its best when the largest volume of water is passing over its brink. From careful study I am satisfied that well over one million horsepower more could be diverted, and not an iota of injury would be done to the scenic grandeur of the cataract if a little engineering skill were used in placing the proper brakes and deflectors. If this is true, think of the tremendous increase in national efficiency and preparedness this development would mean. Arrange now with Canada for a development of water power at Niagara three times as great as at present—the time is ripe.

For every one hundred thousand horsepower diverted, provide that say ten thousand horsepower shall be devoted to the fixation of atmospheric nitrogen. The more varied the methods used the better. Make Niagara the commercial research laboratory of the nation in this field by supplying private enterprise with power at nominal cost for this purpose. Under these conditions, power, even if developed by private enterprise in large amounts, could in the above percentage be supplied as cheaply if need be as Norwegian power, and would be infinitely better adapted and centralized for the purpose. Such power would be within a night's ride of Washington, New York or Chicago. Already located at Niagara is the largest group of electrochemical workers in the world. Such a development would double their number. Is it through lack of foresight or "a dog in the manger policy" that some of our largest and most important electrochemical industries are even now compelled through lack of cheap power to go to Norway and other fields, there to start the training of a foreign army of electrochemical workers upon foreign soil, while unused water which could be utilized without injury goes to waste?

I have been told that the Niagara River is a border stream; that plants situated near that border would be particularly open to foreign attack. Conceding only that Eng-

land be our enemy, this is true. But did Germany give heed to an even stronger reason against making her experimental and peaceful development in Norway, where as at Niagara the economic conditions were right?

Not in a day, a month, nor a year can these problems, alike of peace and war, be worked out, the equipment developed and installed, and above all, the workers trained. The goal is an ever-increasing internal independence both as regards food and chemicals. For an increasing population this may well mean the regeneration of a worn-out soil, the refertilization of our farm lands from New England to the West with ammonia and nitrates from the air. Every farmer, every bread eater is interested in the result. Let me in this connection read two extracts which I recently clipped from the daily press:

"London, Jan. 21.—The urgent necessity of speeding up the supply of munitions has determined the Government to put into force immediately plans for the dilution of skilled labor with semi-skilled, unskilled and female workers in all controlled establishments. In a statement on the subject in the House of Commons to-day Premier Asquith announced that the Government was convinced that this plan offered the only prospect of securing a sufficient supply of munitions to enable the war to be brought to a speedy and successful conclusion. 'Any lack of munitions,' continued the premier, 'would exact a heavy toll in lives of soldiers. It is quite impossible that foreign supplies can take the place of the home production of munitions, but even if those sources of supply were indefinitely extended, the immense demand thereby caused upon our financial resources and our shipping would present insuperable difficulties.' Premier Asquith stated that both the owners of the controlled establishments and the representatives of the trade unions had loyally pledged themselves to support the Government in the scheme of labor dilution. Considerable progress had already been made in certain districts, but he regretted that what had been accomplished fell lamentably short of the national requirements in the present emergency.

"Brigadier General Crozier has given some figures to the Senate Committee on Military Affairs which should put an end to the movement to have the Government build its own munitions plants. He estimates that the cost would be about \$400,000,000, and that 750,000 workmen would have to be employed. This would supply 1,000,000 men in the field and a reserve of 1,000,000 men with guns and ammunition. General Crozier believes that the Government could do better with private manufacturers, whom he would have the Government encourage. As has been proposed, the Government could supervise the manufacture of arms and ammunition and in a considerable degree regulate prices."

The provision of electrochemists, mechanical engineers and operators in these specialized industries in times of peace as an emergency precaution is fully as important as compulsory military service and should be considered as an element of the same broad plan. My wife says she objects to raising her boy to be a soldier, and yet would be the first to tell him to go to the front if his country needed him. Instead, however, I am training him to be a chemical engineer, where I feel that in times of peace and without economic loss he will be in constant training to serve his country's needs to the highest degree should war arise.

Think you that Germany and Switzerland are only interested in the electrochemical and synthetic dye industries because of their economic value in time of peace? They are of tenfold greater value as measures of preparedness. The same benzol, toluol, caustic soda, nitric acid, chlorine and sulphuric acid used in times of peace for the manufacture of dyes are used in times of war for the various nitro explosives; the same equipment is used and the same army of skilled chemists and workers familiar with the latest details of nitration process are in constant training.

Should we not consider the training of this industrial army, the preservation of our growing dye industry, the development of our water power and electrochemical industries as a matter of particular urgency now as a measure of preparedness for national defense?

Metallic Magnesium

Dr. William M. Grosvenor, consulting chemical engineer, New York City, then presented a paper on metallic magnesium (one of the promising baby electrochemical industries of this country, as the chairman remarked). In the introduction he cleverly offered his "qualifications (or apologies)" for speaking on the subject. "There are but two: The first is what I do not know about it. The second what I suspect but am not at liberty to tell."

THE ELEMENT

You all know the chemical position and character of magnesium, leading member of the alkali earth division of the second group, atomic weight 24, closely related in its properties on the left with Na 23, on the right with Al 28, with Be 9 above it and Ca 40 below. Note the comparative lightness: Sp.G. Mg. = 1.75, Na = 0.98, Al = 2.6, Be = 1.64, Ca = 1.6. Also the melting points: Mg. = 750 deg., Na = 96 deg., Al = 660 deg., Be = about 900 deg., Ca. = about 760 deg. All are more or less soft white metals, all show great avidity for oxygen, decomposing water more or less readily. None except aluminium has found large commercial use, but of the others magnesium leads the list by a long distance.

USES

Its chief uses are:

Scavenging alloys, i.e. clearing up oxides of other metals and making far denser, cleaner, stronger and more homogeneous alloys. Valuable in aluminium nickel, copper, brass, bronze, etc., and special steels, because of its intense avidity for both oxygen and nitrogen.

Alloying itself, with aluminium or aluminium containing traces of one or more of the other metals, Cu, Ni, Zn, Pb, Bi, Sb, Fe, etc. It greatly modifies crystallography and physical properties, alloys readily with most metals, and melts at a convenient heat.

Illumination, as in military uses for shrapnel trailers, star bombs, flare lights, etc., and in photography for flash-lights. Its easy inflammability (about 800 deg. C.), the high heat of combustion (134,000 cal.), the relatively low heat of vaporization (1100 deg. C.), the intensely white oxide produced and the high temperature of volatilization of this oxide are the essential factors.

MAGNITUDE AND PRICES

How much is used? A far more agitating question than how old is Anne. Records of imports for the year prior to the war indicated 38,000 lb. About 100 lb. a day, therefore, seemed to be a safe production to undertake. Prices before the war had been very steady around \$1.45 per pound, but it seemed reasonably certain that the cost need not exceed \$1 per pound. After the war began the prices being paid for remnants of imported lots quickly rose to \$2.50.

Some of the first demands here were from wholly unexpected quarters, in surprising amounts and at amazing prices. The most urgent, almost pitiful demands, came from quarters that were not even suspected to be interested in the least. One consumer has contracted for 24,000 lb., another for 15,000 lb., these two alone taking for strictly domestic use more than was supposed to be the total importation. There are at least three other buyers of similar quantities, but exact amounts are not yet established by yearly contract, and even at present prices the consumption for strictly domestic use is about 50 tons.

We found that a great deal of the material was being imported under other names and most carefully disguised—secrecy being preferred to economy. Prices as high as \$10 per pound were gladly paid at first for domestic product. For some months then the prices jumped around from \$5 to \$7.50, but every effort was made to reduce conditions to some sort of order by dealing direct with the consumer. This was partly the result of a deliberate policy for better and more intelligent service of the consumer's precise demands as to quality and delivery, but partly also the result of meeting quite unexpectedly the competition of our own product at prices from 25 per cent below to 50 per cent above the prices we had made. Some of New York's clever war brokers added 10 per cent each through a chain of four or five middlemen. Others assumed direct quotations to have already been through this process and knocked off 20 per cent, trusting that "real cash business" would squeeze down the middlemen they supposed to exist and still leave 5 per cent for the real seller. Now, however, for a number of months the price has been practically fixed at \$5.50 per pound of "guaranteed 99 per cent," actually about 99.5 per cent. Occasionally a lot that has been picked up in the antebellum market for speculation is let go at lower figures or a lot of lower-grade material comes on the market from abroad, but there is practically no volume of these sales.

In spite of the beautiful appearance of the German bars they rarely exceeded 98 per cent and often fell as low as 96 per cent. The process of extrusion concealed impurities by drawing them out into minute threads. It is safe to say that the regular commercial grade of metal made here now is superior to anything ever imported.

REASONS FOR THESE PRICES

It may seem ridiculous to ask or pay such prices. Let us consider. The alloy market constitutes the bulk of the

business, and governs prices. In aluminium castings, for instance, about less than 2 per cent of magnesium cleans up the aluminium and leaves $\frac{3}{4}$ to $1\frac{1}{2}$ per cent in the casting, about doubling its tensile strength, and quadrupling its resistance to shock or jar. It reduces the cost of machining more than 50 per cent, halving the number of resets on the cutting tool, giving clean cut machine surfaces, and permitting a polish to be secured with the last cut instead of a separate operation. With care, $1\frac{1}{2}$ per cent of magnesium at \$5.50 per pound is all that is needed, i.e. $8\frac{1}{4}$ c. per pound of casting actually required to do the same work. The increase in strength means, in some cases, a reduction in weight of casting of 50 per cent. The reduction in casting weight is generally not less than 25 per cent. The weight of a pure aluminium casting may therefore be reduced if this $1\frac{1}{2}$ per cent of magnesium is used by from 25 to 50 per cent. This is a great saving even at normal prices of aluminium since it amounts to about one-fourth of 20c., or 5c. With aluminium at 60c. it amounts to 15c. worth of aluminium saved for a stronger and more stable mechanical result. The saving in machine work alone when the casting is to require much machine work more than pays for the use of magnesium. So much for the consumer or user.

Now the manufacturer of magnesium has certain considerations (of necessity rather than mere excuse) for the high prices. Cost of production abroad prior to the war approximated \$1 per pound. Sales in England were about \$1.30 and here about \$1.45 per pound. At that time $MgCl_2 \cdot 6H_2O$ was selling for about \$18 per ton. Present prices here are now about \$60, nearly four times normal. Other chemicals used in the manufacture have increased to ten times their normal price.

One other factor, i.e. insurance, must be considered in two forms. First, the insurance against cut prices and dumping that may come immediately upon the close of the war, making the plant and market-development work absolutely worthless. Second, the insurance against partisan interference. As a matter of fact, in the case of two plants not a pound of material from either of which has gone for foreign military purposes so far as we know, there have been repeated efforts at molestation and some serious interruptions. Finally, there is the general consideration of relative price advance as compared with other materials: H_2SO_4 , \$12 to \$60, or five times; nitric, 4c. to 12c., or three times; NaOH, $1\frac{1}{2}$ to $5\frac{1}{2}$, nearly four times; Na_2CO_3 , 1 to 4, and numerous other commodities not directly affected by inability to import.

In considering prices it is well to mention separately export prices. Before the war nearly all the magnesium for England, as well as the United States and France, came from Germany. Since the war both France and England are producing in considerable quantities of excellent purity. This fact and the failure abroad to realize the strenuous conditions here, account for the unwillingness of buyers abroad to pay more than \$3.50 for powdered metal (all the above named prices were ingot or bar).

PRESENT PRODUCTION

At present there is being produced here at two points about all the present alloy market will absorb, and an increase of plant is being made of about 25 per cent the present capacity. One other producer makes only about his own requirements. Two others are soliciting business, but have failed to fill orders—in one case the order is now over a year old and still stands unfilled. All told, we believe the present production is at the rate of something over a million dollars a year, and will be slightly in excess of the present domestic needs.

POSSIBILITIES

The use of the metal for scavenging purposes depends on price of metal compared with price of material to be scavenged. For use with copper, brass, bronze, etc., the magnesium can be used at far higher prices than for steel. But the big consumption of the material can only come when it directly replaces aluminium as the predominant metal in the alloy, and arrives at a correspondingly low price. It makes beautiful castings, machines easily and well, is about a third lighter than aluminium, and can be made about two to four times as strong. The coefficient of expansion reported is practically the same as aluminium. When properly pure (over 99.5 per cent), it is apparently quite as resistant to corrosion as aluminium, equal if not superior in electrical conductivity (about half that of copper), and superior in heat conductivity to aluminium (also about half that of copper).

PROCESSES

1. Reduction of fused $MgCl_2$ with Na.
2. Electrolysis of the fused double chloride, usually $MgCl_2 \cdot KCl$.

3. Reduction with carbon. (Patented.)
4. Electrolysis of dissolved MgO . (Applied for.)
5. Reduction of fused $MgCl_2$ with Al. (Applied for.)
6. Reduction of oxide or carbonate to slag-forming residues. (Applied for.)

And some others.

The first process involves the production of metallic sodium, and we have been using the Castner process for this purpose to satisfy ourselves just what the sodium would cost and what the possibilities in this direction were. Existing conditions, the demand for sodium and sodium peroxide, forbid its consideration with a minimum of about 2 lb. of Na consumed for every pound of magnesium produced and the necessity of producing dehydrated fused $MgCl_2$ to start with.

The second process has been perfected and is very largely used abroad. We have commercially used and studied the process here and, with the cheapest water power and chloride, prices under normal conditions by this process must rule above \$1.

The third process, reduction with carbon, is absolutely fascinating in its possibilities. The product is a black or gray powder. Believing such a product would be valuable, the manufacture was carried out on a scale of about 25 lb. per hour. As the difficulty of selling the product became apparent, much time and effort were devoted to attempts to recover the metal in fairly pure form. Owing to serious objection both on the side of cost and regularity of product this process was superseded.

The other processes will be discussed on some other occasion when the engineering problems they involve are believed to be finally solved in the best way and the patent office has finished considering them. The chemical side of each has been thoroughly worked out, however, so that some conclusions may be drawn from the large laboratory or small commercial operations. These may be of considerable interest.

At least one of the processes appears to be adapted to produce directly metal averaging 99.6 per cent purity in tons per day instead of pounds. Laboratory tests give a raw material cost of 4c. per pound of magnesium, and indicate a fuel cost which approaches 3c. as a theoretical limit, though the practical figure will probably be several times as high. The final selection of various possible engineering means and methods remains to be worked out, but it scarcely seems possible that either labor or repairs should exceed 2c. per pound. Thus if commercial yields maintain the experimental level and three times the theoretical power is commercially required, we have prospects of a net factory operation cost (without interest, amortisation, insurance, patent, administration or selling) of 17c. per pound. If only 75 per cent yield is obtained this net factory cost would be about 22c., or a total cost with all overhead expenses of 35c. and a selling price of 40c. to 50c., according to tonnage.

It may be asked with perfect propriety: "Why talk about it now? Some fool will certainly want you to make a contract with him at lower prices, possibly at 50c. He will not realize that it is only the present price of \$5.50 that justifies or even makes possible the thousand and ten-thousand dollar experiments that have been tried and must be tried again and perhaps again during the next three to five years before the tide turns. You will be pestered for years with this 17c. talk." We have carefully considered this probability. The men who are doing this work do not cultivate talkativeness as a preference. Just at this time, however, certain considerations of public welfare should take precedence of preference. National self preservation demands the subordination of personal interest. If we expect representatives at Washington to jettison the pork barrel, the army post, the high-tide navy yard, and political trading generally, and give us a fighting chance for our lives in the scrap that is certainly coming, we must set the example of considering national interest first. If we are to have the army and navy preparedness for which we have already wasted more money than Germany has paid for her wonderfully efficient fighting machine, if we are to have any preparedness instead of repairs or regrets, we must co-operate with all we have in service, information and suggestion.

Therefore, at the risk of criticism and possible financial sacrifice, it seems to be a duty at this time to point out what may possibly be expected of magnesium. Few realize the extent to which it is valuable in military work. One of the great foreign explosive experts stated that he would be glad to pay \$1.50 per pound for 500 tons. A single contract for shrapnel being executed in this country would require about fifty tons. The illuminating bombs to make daylight over the enemies' works and trenches consume large quantities. The trailer attached to shells serves at night to show the effectiveness of the fire. For all these purposes mag-

nesium produces a result that cannot be approached by antimony or aluminium. Consider what it means to aeroplane, dirigible and motor construction, to high-speed engines of every type, to reduce weight one-third and double strength. A material that has a density of 1.75 and may be hot rolled to 35,000 lb. per square inch or cold rolled very much higher.

Although five or six men are being kept practically all their time on the development of these possibilities, the broad, quick development is a task for the energy of hundreds. Feeling the responsibility which knowledge of the possibility entails it became the duty of those in charge of this work to let others know and be active in their side of preparation, to apply the material.

Liquid Chlorine and Electric Steel

Dr. G. Ornstein, chemical engineer of the Electro Bleaching Gas Company, then read a paper, illustrated by lantern slides, on liquid chlorine. This paper was published in full on page 215 of our issue of Feb. 15.

Dr. George W. Sargent, vice-president of the Crucible Steel Company of America, spoke briefly and, in view of the late hour, promised to present his paper on electric steel at a future meeting of the society.

Electrolytic Zinc

The last paper on the program was by Mr. W. R. Ingalls, editor of *Engineering and Mining Journal*, on electrolytic zinc. In the absence of the author it was read in abstract by Dr. J. W. Richards.

Without any doubt, the most important thing in the metallurgy of zinc in 1915 was the inauguration of electrolytic zinc production direct from ore on a large experimental, even a commercial, scale at several places, the most important of these being at Anaconda, Mont., where the production of electrolytic spelter at the rate of about five tons per day was begun. The results are considered so favorable that the Anaconda company has commenced the erection at Great Falls, Mont., of a plant capable of producing 35,000 tons of electrolytic spelter per annum. With regard to the nature of the Anaconda process, Mr. Laist, who is responsible for it, has written me as follows:

I can hardly claim that we have accomplished anything especially new in this line, except in so far as we have done on a somewhat larger scale what had often been done before by others in the laboratory in a smaller way. Briefly, the process consists of concentrating the zinc ore, preferably by flotation, so as to make a concentrate with as little insoluble matter as possible and as rich in zinc as the nature of the ore allows. This concentrate is roasted in two of the furnaces of our copper-leaching plant, so as to produce a calcine containing from 2 to 3 per cent sulphur, most of which is present as sulphate sulphur. The temperature is not allowed to exceed 1350 deg. Fahr., under which conditions the formation of zinc ferrite is not pronounced.

The calcine, after cooling, is treated with a solution containing sulphuric acid, which dissolves the zinc and a little of the iron. A small amount of manganese dioxide is added for the purpose of oxidizing the iron, which is then precipitated by means of a small amount of powdered limestone. Any arsenic or antimony is carried down by the precipitated ferric hydroxide. The resulting solution contains nothing but zinc, cadmium and copper, and is separated from the residue by filtration. The residue contains the lead, silver and gold and part of the copper originally present. The solution is treated with metallic zinc to precipitate the copper and cadmium, and is then pumped through a clarifying filter-press into a storage tank, from which it goes to the electrolytic cells. The cell room contains forty-two tanks, which are in no way different from those commonly used for copper refining. Here the zinc is deposited on aluminium plates.

The solution from the cells contains sulphuric acid and is used for leaching a fresh charge. The zinc deposits on the aluminium plates are stripped off every 48 hr. and sent to the melting furnace. At the present time we are making about five tons of zinc per day of a high degree of purity.

I will add to this that the leaching is performed in Pachuca tanks, the lixiviant being spent electrolyte plus the quantity of fresh acid required. The anodes of the electrolytic cells are of pure lead. The solution is electrolyzed at a current density of 20 to 30 amp. per square foot of cathode surface, the general practice being about 23 amp. The voltage drop per cell varies from 3.8 volts at the head cell of the series (21 cells in cascade series) to 3.4 volts in the tail cell. Current efficiency is from 93 to 94 per cent.

Apart from the Anaconda work, the most ambitious plans carried on in 1915 were those of the Consolidated Mining and Smelting Co. of Canada, which continued the experi-

mental work begun several years ago. In the last official report of this company it is stated that spelter of good grade has been produced at the rate of 1000 lb. per day from ore from the Sullivan mine, and that the results were sufficiently promising to warrant the building of a plant capable of producing 25 to 35 tons of spelter daily. Construction of this plant is well advanced, and it is expected to be in operation early in 1916.

Electrolytic zinc was also produced in 1915 on an experimental scale by the Electro Zinc Co. at Welland, Ont., while some work in this line was done at Keokuk, Iowa, and at Bully Hill, Cal., and there were one or two other operations (one of these employing the Isherwood process) that may not yet be mentioned publicly. The work at Welland is unique in that the dissolving of the zinc and the electrolysis of the solution is performed in the same vat, the cathodes being inclosed within canvas bags. All of the other work, so far as I know, is being done on lines similar to those at Anaconda.

Before going any further, let it be well fixed in the mind that the conditions that have existed in the zinc industry during the last year are not only unprecedented but also it is certain that they cannot be otherwise than ephemeral. They have been due to a shortage of metallurgical capacity, not of ore in the least degree, and that shortage is being reduced with extraordinary rapidity. In the meanwhile, however, there has naturally been a huge metallurgical margin—even \$60 per ton of ore against a normal of about \$15—in the manufacture of common spelter and with such a margin it has been good sense not only to commit metallurgical crimes, but also to institute new processes that would not ordinarily be profitable. In the manufacture of high grade spelter the margin has been much higher, so much so that the possibility of it would two years ago have been considered nothing less than preposterous.

Now, the electrometallurgy of zinc is no new thing. The electrolytic refining of impure spelter was tried on a large scale by Nahnhen in Upper Silesia in the '90s, the hydrometallurgical-electrometallurgical treatment of zinc ore was essayed disastrously by Ashcroft at Cockle Creek, New South Wales, in a works costing about one million dollars. Dr. Hoepfner developed a process that was put into use at Führfort on the Rhine and at the works of Brunner, Mond & Co., at Winnington in England. At the former it has been abandoned after a short time; at the latter it has been continued through a long series of years, making a few hundred tons of spelter annually, and is in use at the present time. The electrometallurgy of zinc has therefore a commercial history of respectable antiquity.

In the early days of the art, both commercial and experimental, difficulty was experienced in obtaining dense deposits on the cathodes, spongy zinc being a stumbling block, but while this matter required some study for its mastery, it was manifest that the real difficulties of this process were the getting of zinc into solution rather than out of it, and the large amount of power required for zinc precipitation.

With regard to the former point, I refer to the formation of insoluble ferrite of zinc in roasting, with the consequence of relatively low extraction of zinc. That is experienced in the case of many, perhaps most, ores that it is desired to treat. To illustrate, roasted Joplin blende may be leached with sulphuric acid so as to cause it to give up 97 or 98 per cent of its zinc, the residue being a white silica sand, but nobody wants to treat Joplin ore by a hydrometallurgical process for the reason that it would be less economical than ordinary smelting. On the other hand, certain mixed ores high in iron like those of Leadville, Col., may give up only about 65 per cent of their zinc. So low an extraction would in itself be prohibitive in most circumstances in ordinary times. It is possible that the roasting might be conducted in such a way as to steer clear between the Seylla of zinc ferrite on the one hand and the Charybdis of undecomposed zinc sulphide on the other hand, but that question has not been investigated with definite results, so far as I know. With regard to the high power required for the electrolysis of zinc solutions with insoluble anodes, the expense of it, when imposed upon the cost of roasting, leaching, remelting cathodes, reworking of products, etc., is likely to make the cost of hydrometallurgical-electrometallurgical zinc extraction too high to be ordinarily considered.

I have, therefore, repeatedly expressed the opinion that metallurgical processes of this sort were unlikely to be successful commercially unless: (1) Exceptionally cheap hydroelectric power, such as the \$6 or \$7 per annual horsepower of Norway and Sweden were available; or (2) unless use could be made of the anode reaction, such as the

*Compare, however, the figures given by Mr. C. A. Hansen on the results obtained at Bully Hill (this journal, Feb. 1, p. 120).—Editor, MET. & CHEM. ENG.

liberation of chlorine by the electrolysis of a chloride solution and the employment of it for some chemical manufacture, as at Winnington, England; or (3) unless certain especially favorable conditions otherwise existed. By the last I mean such things as high grade of the run-of-mine ore, a kind of ore that will give up a high percentage of zinc by lixiviation with sulphuric acid, an ore high in silver, and possibly lead. These points are almost determinative. In the pyrometallurgy of zinc the extraction of silver is, perhaps, about 65 per cent. In the hydrometallurgy of zinc it ought to be upward of 90 per cent, perhaps as high as 95 per cent. The situation with respect to lead is somewhat similar. It is needless to dwell upon the importance of this in the cases of ore exceptionally high in silver.

Now, in the treatment of the Butte ore at Anaconda, about all of the favorable conditions that I have enumerated under the third head exist. The ore raised from the mine is of rather high grade, it is of a character that enables 90 per cent of the zinc, or more, to be extracted by sulphuric acid lixiviation, and as zinc ores go, it is exceptionally high in silver (the concentrated ore going 20 oz. silver per ton, or thereabouts). Moreover, the Anaconda company is introducing zinc extraction in connection with its other great metallurgical work, thus dividing general and administrative expenses, etc. It is able to obtain moderately cheap power at Great Falls, and finally, what is not least in importance, it possesses about the best metallurgical organization of any concern in the United States, and is instituting this new process at a time when there ought to be commercial profit in spite of any imaginable infantile disorders. I am not free to communicate such figures respecting the Anaconda results as I know, but I may say that the Anaconda management is thoroughly aware of the exceptional conditions existing in the zinc industry at present and is nevertheless of the opinion that with its peculiarly favorable circumstances it can continue the production of electrolytic zinc in competition with everybody else in the normal times, or even in the hard times that may be experienced after the termination of the war. The promise of the development of the hydrometallurgy-electrometallurgy of zinc as a commercial art on a large scale has, therefore, already become a prospect. There is to be such an art. The magnitude that it will attain, and its effect upon the zinc industry of the world, remain for the future to tell, but that it is going to have an early and important influence is not to be doubted.

Turning attention to some of the technical features of electrolytic zinc production, the conditions governing the electrolysis of zinc solutions were exhaustively treated by Dr. Victor Engelhardt in a paper read at the first general meeting of the Gesellschaft Deutscher Metallhütten und Bergleute and published in *Metallurgie* a few years ago. A summary of Dr. Engelhardt's conclusions, together with some additional notes, was published by Prof. J. W. Richards in "Transactions of the American Electrochemical Society, XXV," pages 281-290. The ideas of Dr. Engelhardt, who is the chief engineer of the electrochemical division of the Siemens & Halske Company of Berlin, are exemplified in what are called the Siemens & Halske and Isherwood processes. However, in the late development of zinc electrolysis "processes" and patents have played but slight part. With recent experimenters the matter of spongy zinc deposits appear to have been among the least of the difficulties. Mr. Keating succeeded several years ago in depositing smooth, solid zinc on his cathodes at Bully Hill, Cal., while as for Mr. Laist, he accomplished this part of the process as a matter of course, just as simply as if he were depositing copper, the necessary precautions as to purity of solution, etc., being naturally taken.

With regard to the grade of electrolytic zinc, high purity is easily obtained. This is something that is far more under control than in refining by fractional distillation. Lead ought not to go appreciably into solution at all, while iron, copper and cadmium—the other common impurities of spelter—are readily precipitated from the solution. The spelter first made at Anaconda was higher in cadmium than is permitted by the standard specifications for "high-grade." At that time zinc dust, more or less impure, was being used as the precipitant for cadmium. Running the clarified solution through a tube mill filled with zinc balls corrected this, and the grade of the spelter was then raised to upward of 99.9 per cent. Brunner, Mond & Co. have been for many years guaranteeing their electrolytic spelter at 99.95 per cent, and there is no reason why the Anaconda spelter should not be made as good as that.

Is electrolytic zinc extraction going to revolutionize the metallurgy of zinc? Unqualifiedly, no. When the zinc industry returns to its normal status, conditions will be in the main as they were before the war, and the principles that I have previously stated will continue to obtain, with

the difference that some people will have learned the details of the art, will have gone through the period of infantile mistakes in a time when almost any mistake was of no great consequence. By that time some of the concerns possessing exceptionally favorable conditions—Anaconda, if any—may be able to continue. Others will not.

However, there are certain new industrial features that can not yet be clearly estimated and may have a modifying effect upon this forecast. One of these relates to the matter of high grade zinc. Previous to the war that class of spelter was produced in limited quantity and sold at a premium over common spelter of about 2½c. per pound. Inventors, promoters and others who talked about making such zinc were discouraged from reckoning upon the premium by the dictum that the market would not take any more than the then supply, which was indeed artificially limited, and that it was unsafe to count on anything but the price for common spelter. During the war high-grade spelter has fetched 40c. per pound, and at times the demand for it has been insatiable. This demand has been especially in connection with the manufacture of ammunition and may be expected to cease with the war, but will the advertising that high-grade spelter has had and the wider knowledge of its peculiar properties that has been acquired give it a more extensive use in the peaceful arts and a maintenance of the premium for it that will be to the advantage of the electrolytic producer? Or, will it become a drug in the market, with entire disappearance of price differential? These are questions that nobody yet knows enough to answer reasonably.

Another new and uncertain factor is the bearing of the flotation process of ore concentration upon the metallurgy of zinc. I think that this had a good deal to do with the institution of the Anaconda work. About all metallurgical work is a sequence of steps of concentration and refining, treating the bulk of the ore by a cheap but wasteful process and delivering a concentrated product to a more costly but less wasteful process. Now, most experimenters in the hydrometallurgy and electrometallurgy of zinc heretofore have contemplated the application of a costly process to the run-of-mine ore. The flotation process has enabled ore to be concentrated at relatively small cost with but slight loss. Let it be observed, therefore, that Mr. Laist is applying his costly process not to run-of-mine ore, but to a flotation concentrate in which about 90 per cent of the zinc is concentrated in about one-fourth of the original weight. This is the new and important feature of recent zinc electrolytic work.

We must let our thoughts run a little further ahead. The treatment of flotation concentrate is one of the present troubles of the zinc smelter, owing to its excessive fineness, which produces difficulties that it would take me too long to describe. Yet the proportion of this class of ore that the zinc smelter is getting is still relatively small. The supply of it is, however, bound to increase, and when it becomes large the troubles of the zinc smelter will really begin. Now the hydrometallurgist will have the same troubles up to and through the roasting of the ore, but he will be free from those that arise in the distillery. In so far he will have an advantage over his brother pyrometallurgist, but whether it will be a weighty advantage I do not venture to offer an opinion.

Another thing that may help the hydrometallurgist is improvement in the method of roasting. Twenty-five years ago he used to talk about sulphate roasting. He did not in practice find the idea to work out as well as he expected. While he might be able to render 40 or 50 per cent of the zinc soluble in water, he found there was too much undecomposed sulphide left behind after leaching with sulphuric acid. So then he said he would roast the ore, completely leach all the zinc with sulphuric acid and be done with it. To his surprise he found that much of the zinc had been rendered soluble by the formation of zinc ferrite if iron were present in the ore, as was almost always the case. The roasting of ferruginous blends in such a way as to convert all of the zinc into sulphate and oxide, avoiding both sulphite and ferrite, which may perhaps be done by correct control of temperatures, perhaps by some other control, is an interesting subject for investigation. Mr. Laist has given some attention to this by carefully limiting the temperature of his roasting furnace. However, I think that perhaps the danger of ferrite formation is not very great in the case of his ore. Anyway, I know that it is not in roasting some similar ore of Butte without much regard to the matter of temperature.

In view of the very late hour the discussion was very brief. In reply to a question by Dr. Baekeland, Mr. Landis replied that the cost of getting nitrogen gas from liquid air is one of the smallest cost items in their cost sheet.

The Operation of the Blast Furnace

BY J. E. JOHNSON, JR.

(Concluded from Page 215)

The Progressive Changes in the Ascending Gas Column

Turning now to the changes in the gas column, we find that these are of three separate kinds, but owing to the fact that the physical state of the gas does not change they are less sharply divided into zones than in the case of the solid and liquid materials. The three kinds of change are chemical, thermal, and physical. That is, change in composition, in temperature, and in pressure and density of the gas.

Considering first the chemical changes we have the blast entering, in coke practice, in a highly heated condition at the tuyeres, and in good practice distributed by their action with approximate uniformity over the tuyere zone from which it rises through the coke column, at first being converted to CO_2 , but as it rises from the tuyeres the gas is exposed to an excess of carbon precisely as in a producer bed with the result that the CO_2 quickly breaks down, the additional supply of carbon taking from the CO_2 half its oxygen and reducing the whole to CO. With the blast enters a certain amount of water vapor, and this is instantly dissociated by the incandescent fuel into hydrogen and oxygen, the latter uniting with the fuel exactly as if it entered in the form of oxygen, the hydrogen rising through the lower zones of the furnace as such, but meeting with different fortunes in the upper regions according to the conditions.

We have already seen that the combustion of all the oxygen of the air to CO is complete at the top of the bosh, and as it rises from this point it is progressively exposed to ore containing more and more oxygen, from which the gas progressively removes this element, converting a portion of the CO into CO_2 .

It is well to reiterate here, what I have tried to make clear in earlier chapters, that the ratio of CO and CO_2 in the issuing gases does not depend upon any equilibrium diagram no matter how scientifically derived, but upon the simple arithmetical fact that each unit of ore requires for its final reduction and melting in the hearth a certain quantity of hearth heat, for the production of which a certain definite quantity of fuel is necessary, an amount which can easily be calculated if the conditions are given. This fuel is, as we have seen, burned to CO in the hearth, the unit of ore contains a definite quantity of oxygen, and this quantity of oxygen combining with the given quantity of CO produces a mixture of CO and CO_2 , of

FIG. 1—PERCENTAGE CURVE OF CO_2

FIG. 2—PERCENTAGE CURVE OF CO

a composition depending purely upon chemical arithmetic, at least within limits far beyond those which we have ever reached. This condition is somewhat modified by the amount of solution loss of fuel which occurs, and this does depend, among other factors, upon the relative concentration of the two gases, but it cannot be too strongly emphasized that the arithmetical relation rather than the chemical equilibrium is the predominant factor in determining the ratio of the top gases.

When we reach a certain point in the furnace the rather slow and orderly change of gas composition takes a sudden turn, the percentage of CO_2 increasing quite rapidly, this increase coming from the CO_2 driven off from the limestone by the heat of the furnace exactly as in a lime kiln.

Figs. 1, 2 and 3 are reproduced from *Stahl und Eisen*, Vol. 31, Fig. 1 from an article by W. A. Schlesinger, Figs. 2 and 3 from one by M. Levin and H. Niedt. These are based upon experimental determinations made by sampling the gas at different heights in the furnace through holes drilled in the wall.

Fig. 2 shows the sudden rise of CO_2 quite plainly, Fig. 3 does not show it, although there is an increase in the rate of rise of the curve in one region, and Fig. 1 shows an absolutely uniform rise of CO_2 , after a sudden increase just above the top of the bosh. These figures are given because of the scarcity of experimental data of this kind, and because experimental data even though they be not representative of our conditions are better than purely theoretical illustrations.

At the same time these curves are all lacking in a strongly marked feature which I found with unmistakable plainness in the course of some experimental work. This is the fact that when CO_2 is driven off from the limestone it at once attacks the carbon vigorously, and a part of it is reduced back to CO so

FIG. 3—PERCENTAGE CURVE OF CO_2

that the concentration of CO, at the top of the furnace is considerably less than it is at a point somewhat lower down. This fact was determined by running a 6-in. pipe down through the center of take of a furnace with the Longdale type of top, to a point some 8 or 10 ft. below the stock line, and taking simultaneous samples of the gas discharged through this pipe and that at the top of the furnace. Determinations were made several times, and with a result broadly the same in every case.

This, it must be admitted, is to some extent a contradiction of my statement above that the equilibrium ratio was of minor importance in determining the composition of the top gases, because obviously here we have an established equilibrium disturbed by outside conditions and automatically restoring itself. But my impression is that, as intimated above, this is a matter affecting the solution loss of the coke rather than the equilibrium between the iron ore and the gas composition. It is, moreover, probable that this condition was much more marked in these two furnaces than in many others for three reasons, that the ore was lean, and the quantity of limestone charged, and of CO, disengaged, therefore very large; that the top of the furnace was quite hot, and that the coke was distinctly of a soft and, therefore, readily soluble variety. There can, however, be no doubt that this tendency exists. I believe that the same result has been obtained by other observers sending pipes down from the top of the furnace, but I have no data as to these tests.

TEMPERATURE CHANGES IN THE ASCENDING GAS COLUMN

Figs. 1, 2 and 3 each show a scale of temperatures at different elevations taken through the same observation holes as the gas analyses, but I am unable to accept the temperature given for a point just above the tuyere plane, 2012 deg., as correct, because this is the hottest zone of the furnace and must be at least as hot as the issuing iron and slag which in ordinary coke practice are from 2650 deg. to 2850 deg.

This temperature has been obtained by many hundreds of direct pyrometric observations on issuing iron and slag at several blast furnaces. This is a line of work which has been too little followed, partly because of the lack, until very recent years, of pyrometers of sufficient accuracy to inspire any respect, and partly because of indifference on the part of furnacemen. It is gratifying to note that at the extensive test of titaniferous ore at Fort Henry a pyrometer expert was employed to make observations of the temperature of running iron and cinder, and it is a matter of much satisfaction to the writer that the results of these accurate tests indicated a temperature of about 2800 deg. on this experimental run using all magnetic ore (which requires more fuel and a hotter hearth than softer ores), as against the figure of 2750 deg. obtained by me as the result of many thousands of observations with a much less accurate instrument, a number of years ago, on a furnace working a more reducible, though leaner ore, and almost certainly running with a somewhat colder hearth.

Another reason for mistrusting the data given in Figs. 1 to 3, particularly Fig. 1, is that the drop in temperature from a point just above the tuyeres to the top of the bosh is given as only 100 deg. C. or 180 deg. Fahr., whereas all the facts of practice, above all observations on blown-out furnaces, indicate by the condition of the walls at these points that a far greater difference in temperature between them has existed. For instance, when iron-pipe cooling blocks are used, the cast iron around the wrought pipes is

FIG. 4.—PRESSURE TEST ON NO. 4 FURNACE AVERAGE OF 25 READINGS

frequently entirely melted away so that the pipe runs naked in the furnace, in and just above the tuyere plane, while precisely similar blocks at a plane 10 or 12 ft. above are not only perfect in shape, but frequently look when they are taken out at the end of the blast as though they had never been used.

From the top of the bosh upward we have a practically uniform drop in temperature to that at which the gas is discharged, this depending as shown in the last chapter upon the thermal conditions of the operation, the total drop being roughly proportional to the iron produced per ton of fuel.

CHANGES IN THE GAS PRESSURE

Here fortunately all speculation can be laid aside, for owing to the kindness of Mr. Reese I am able to present a diagram, Fig. 4, giving the results of 85 sets of observations of pressure made at holes cut at different levels in one of his furnaces.

There will be seen first a quick drop from the tuyere pressure. This is the penetration drop described in a previous article. From this point on we have a practically straight line drop to a point quite close to the top when the rate of drop slows down, and the curve becomes concave to its base line. This is not due to any change in the law of pressure-drop but merely to the fact that the top of the stock is not a level plane but a conical crater, probably 8 or 9 ft. in depth. The gas pressure begins to be relieved at the bottom of this in the center, but, of course, there is still some resistance and therefore some pressure at the circumference of the furnace at any point below the top of the crater, hence the tapering off in the rate of the drop.

These observations were all made when this furnace was working regularly and properly, but Mr. Reese has also had observations made when the furnace was working irregularly, shown in Fig. 5, and these are equally instructive, if not more so. It will be seen that there are regions in which the pressure drops very rapidly indicating a decided constriction at this point followed by a rate of drop slower than the average, indicating that above the obstruction the gas had ample room to slow down and so reduce the friction drop.

Whether the sudden pressure drop was due to abnormal changes in the charge and produced the irregular working, or whether a partly scaffolded condition produced the sudden pressure drops it is virtually impos-

FIG. 5—PRESSURE OF FURNACE MOVING IRREGULARLY

sible to say, but bearing in mind what has been said about the importance of uniform flow of gas, from the practical point of view in cutting down dust losses and the like, the very serious results which must follow from these irregular pressure conditions become obvious, and it is a matter of no surprise that the furnace working under these conditions should produce unsatisfactory results. On the other hand, the extremely smooth curve was obtained as the result of many observations on a smooth working furnace, and its regularity (which must be a matter of surprise to those accustomed to the many minor changes which even a good working furnace makes) indicates that a uniform and regular pressure drop is both the condition and the product of smooth and regular working.

These extremely valuable and interesting results have never before been published and I feel that Mr. Reese has placed not only me but the other members of the profession under a lasting debt of gratitude by so generously allowing their publication here.

SHAPE OF PRESSURE CURVE

The rate at which the pressure drops is a matter of some interest. The shape of the curve of decreasing pressure in a pipe line given by the formula quoted in the last chapter, and established by experiment, is a parabola, the pressure falling slowly at first and more rapidly afterward, just as a horizontally thrown ball does under the influence of gravity. The same should be true of the curve of pressure drop in the furnace because in it as in the other the difference of the squares of the pressures is proportional to the resistance.

Mr. Reese's curve is almost exactly a straight line. One cannot help but wonder if a slight increase in the bosh diameter yielding a lower rate of pressure drop at first, and a proportionately somewhat more rapid one later, would not give a closer approximation to the theoretical parabola, which would correspond with a more nearly uniform velocity, and might easily result in slightly better working for reasons pointed out in the last article.

The spring meeting of the American Chemical Society will be held at Urbana, Ill., from April 18 to 21. That of the American Electrochemical Society at Washington, D. C., from April 27 to 29.

Work on the Federal Trade Commission

The value of technical associations to technical men are well known to most of our readers. That business associations are equally as valuable to business men was brought out in an address by EDWARD N. HURLEY, vice-chairman of the Federal Trade Commission, before the annual meeting of the Rubber Club of America, in New York, Feb. 2, 1916. Mr. Hurley discussed the work of the Federal Trade Commission and showed how the Government could assist business if it had the necessary data. The commission is constantly receiving requests for information on how to improve conditions, and to meet unfair competition. Upon investigation the Commission found that detailed data was nowhere available which would enable them to pass on the underlying difficulties. The Commission in order to co-operate is preparing a few simple questions pertaining to their industries which they will submit to the business men in a few weeks.

Mr. Hurley said the collecting of statistical data could best be done by the Government on account of its facilities and the confidence felt in it by business men. There are about 250,000 business corporations in the country and over 100,000 of these report no net income whatever. In addition 90,000 make less than \$5,000 a year, while only 60,000 make \$5,000 a year or over. In tabulating data on the successful corporations the Commission found that out of 66,000, 30,000 charged off no depreciation whatever and this demonstrated the need of a thorough study of our industries and a necessity for better accounting methods. Price cutting and demoralization of many industries has been done without an adequate knowledge of cost. The Commission hopes to improve conditions by indorsing standard systems of bookkeeping and cost accounting and by assisting in devising standard systems either at the requests of individual concerns or representative associations.

In the field of standardizing products, processes, and raw materials much has already been accomplished. Many industries have adopted specifications to which practically the whole industry conforms. Much of all this has been brought about by associations, but we have made only a beginning. In Germany every important industry is organized into trade associations and 85 per cent of the manufacturers are represented. The old adage "In unity there is strength" is put into practice, and has proved to be the backbone of Germany's industrial and commercial achievements. More than 600 independent associations of manufacturers, producers and merchants are in existence there.

Coming Society Meetings

The American Institute of Electrical Engineers has extended a courteous invitation to the New York Section of the American Electrochemical Society for a meeting on "corrosion" (with special reference to the electrolytic corrosion of underground structures). The meeting will be held on the evening of March 10 in the lecture hall of the United Engineering Societies Building, 29 West Thirty-ninth Street, New York. The two principal speakers will be Dr. Burton McCollum of the Bureau of Standards, Washington, D. C. (representing the A. I. E. E.) and Professor William H. Walker, of the Massachusetts Institute of Technology (representing the A. E. S.).

A meeting of the New York Section of the American Chemical Society will be held on the evening of March 10, in Rumford Hall, Chemists' Club. At this meeting the Nichols medal will be awarded.

A meeting of the New York Section of the Society of Chemical Industry is announced for March 24, to be held in Rumford Hall, Chemists' Club.

The Bureau of Mines Work on Manufacture of Gasoline and Benzene-Toluene from Petroleum

The researches of Dr. W. F. Rittman of the Bureau of Mines, on the production of gasoline, benzene, and toluene from petroleum and other oils have deservedly attracted such a widespread attention that the first complete official publication of the results of this whole series of researches will be exceedingly welcome. It is being published as Bureau of Mines Bulletin No. 114, and is entitled "*Manufacture of Gasoline and Benzene-Toluene from Petroleum and other Hydrocarbons*," by W. F. Rittman, C. B. Dutton and E. W. Dean, with a bibliography compiled by M. S. Howard. From press sheets of this Bulletin the following is taken.

In the preface to the Bulletin some interesting figures on gasoline production are given, taken from a report made by the Secretary of the Interior to the U. S. Senate under date of Feb. 21, 1916, and published as Senate Document 310.

The estimated production of gasoline in the United States for 1915 was 41,600,000 barrels, the amount exported 6,500,000 barrels, leaving 35,100,000 barrels for domestic consumption. The consumption is estimated to have been 25 per cent greater than in 1914. The Secretary of the Interior says the increased cost of gasoline is due to increased domestic consumption, increased exports, decreased production of crude oil containing a large percentage of gasoline, the increase in the price of crude oil and financial influences. The preface states that on Feb. 1, 1916, seven refineries, in six States were installing plants for the Rittman gasoline process, and that benzene and toluene were being produced in large quantities by the other process.

Part I of the Bulletin which comprises 126 pages is entitled "The Cracking of Oils: Principles Involved and Methods of Treating Recovered Products." After taking up the consideration of the present demand for gasoline a historical review of older patented cracking processes is given. This is followed by general considerations on the uses of benzene and toluene and other aromatic hydrocarbons in dyes and explosives and a review of patented processes for their production from petroleum. A complete account of the laboratory experiments made in Columbia University, which led up to the commercial development of the processes is then

given. The results of the experiments led to the following conclusions:

In procuring the desired products of the cracking reaction, the physical and chemical properties of an original oil are of secondary importance compared with the influence of temperature, pressure, time, and concentration.

Under like conditions, practically identical results have been obtained from five different oils, and the differences reported may be attributed, in part, as much to variation in rate of reaction as to the actual production of dissimilar equilibrium products. One exception noted relates to the production of carbon, a residual product, the formation of which seems to be proportional to the quantity contained in the original oil. Viscosities and specific gravities of the oils obtained show in some measure the influence of the properties of the original oils, but the differences are only slight and can perhaps be explained by the system not having been allowed to reach complete equilibrium.

The experiments have indicated the commercial possibilities and advantages of hydrocarbon reactions carried out in a cracking chamber composed of a vertically arranged tube, when the products to be treated are in a gaseous state and are cracked in an atmosphere of decomposition products. The results obtained with large-scale equipment, subsequently described, have demonstrated the correctness of these conclusions.

In connection with these experiments it was also proved that it was possible to make trinitrotoluene from toluene derived from petroleum with as high a melting point and as pure as that from toluene derived from other sources. The method developed was a modification of the two-stage process, producing first mononitrotoluene with subsequent purification and conversion into the trinitro derivative.

Experiments on the cracking of pure hydrocarbons followed by a confirmatory test using petroleum led to the following conclusions: From cymene it is possible to produce by "cracking" all the other hydrocarbons of the series, such as xylene, toluene, benzene, naphthalene,

GENERAL VIEW OF THE IRVINE PLANT, AETNA CHEMICAL COMPANY, PITTSBURGH, PA.

LABORATORY AT DEVELOPMENT PLANT, SHOWING TYPE OF DISTILLATION APPARATUS USED IN TESTING CRACKED OIL

and anthracene. From xylene results toluene, benzene, naphthalene and anthracene, but no cymene. Toluene yields benzene, naphthalene and anthracene, but no cymene and no xylene. Benzene goes to naphthalene and anthracene, but not to any of its higher homologues. From naphthalene anthracene is readily obtainable, but none of the monocyclic hydrocarbons, benzene, toluene, xylene and cymene is produced. Anthracene yields no naphthalene, but goes to tarry matter, carbon and gas.

Likewise it appears that the formation of higher benzene homologues is favored by less strenuous conditions of cracking than constitute an optimum for benzene. Polycyclic hydrocarbons are shown to be decomposition products of monocyclic hydrocarbons, as production of the latter falls off under cracking conditions that favor the formation of such typical compounds as naphthalene and anthracene.

On the basis of the evidence at hand it seems justifiable to state that the course of the cracking reaction in the aromatic series may be indicated as follows and that practically no reverse action occurs.

Higher benzene homologues $\rightleftharpoons$ lower benzene homologues $\rightleftharpoons$ benzene $\rightleftharpoons$ (diphenyl) $\rightleftharpoons$ naphthalene $\rightleftharpoons$ anthracene $\rightleftharpoons$ carbon and gas.

APPLICATION TO OTHER FIELDS OF PRINCIPLES ESTABLISHED BY HYDROCARBON REACTIONS

The technical and industrial importance of these different reactions is much greater than their application to the treatment of petroleum alone would indicate. The principles involved are equally applicable to the treatment of coal, lignite, peat, bitumen, or any other substance capable of yielding liquid hydrocarbons. In fact, the field for application of these principles is even greater as regards these other substances because of their greater extent and production. The output of petroleum in the United States, although 65 per cent of that of the whole world, is decidedly secondary, on

the basis of volume and tonnage, to that of solid fuels, indicating at once the tremendous possibilities in the production of tar and other hydrocarbons from coal and the other materials enumerated.

In view of the widely varying percentages of the different aromatic hydrocarbons obtainable from a crude oil, and in view of the course of reactions among aromatic hydrocarbons, a most significant feature is that there are present in the tars resulting from most present-day distillations of coal a small percentage of low-boiling aromatic hydrocarbons, such as benzene and toluene, and a very large percentage of aromatic hydrocarbons of large molecular weight such as naphthalene and anthracene. The latter undoubtedly are formed in some stage of the operation from monocyclic aromatic hydrocarbons. In practically all coal tars there is less than one part of toluene to three parts benzene. It is furthermore common information that naphthalene, methyl-naphthalenes, methyl-anthracenes, anthracenes, etc., are present in large proportions. In the light of the investigations reported, which unquestionably indicate the course of reaction to be first in the formation of the higher members of the benzene series, then progressively to the formation of toluene, benzene, naphthalene, anthracene, carbon and gas, it is to be concluded that practically every present coal-distillation process carries the cracking to the point of ruinous decomposition of benzene and toluene in the formation of the higher boiling aromatics. The Bureau of Mines is at present investigating this feature.

LARGE-SCALE WORK

The second part of the Bulletin comprising 81 pages deals with the large-scale development of the benzene-toluene and gasoline processes. The following is abstracted from the second part:

On March 9, 1915, a contract was entered into with the Aetna Explosives Company, who agreed to spend

ARRANGEMENT OF OIL FEED INTO CRACKING TUBES

\$200,000 in the development of the process. Applications for patents on the processes were filed in March, 1915, and it has been decided to have the patents administered by the Secretary of the Interior who will issue licenses to those desiring to use the processes. No royalty or other monetary payments will be required. Although the use of the processes is to be free of charge to all citizens of the United States, it has been considered necessary for the protection of the basic patents, that licensees shall assign to the Secretary of the Interior, as trustee, all patentable improvements, relating to the processes, that may be developed by them during the employment of the process. A provisional form of license has been adopted while the patents are pending. For any information as to licenses application should be made to the Director of the Bureau of Mines, Washington, D. C.

Large-Scale Development of Benzene-Toluene Process

Under the terms of the agreement with the Aetna Explosives Company the work incident to the development of the benzene-toluene process on a scale of commercial magnitude was begun at Pittsburgh, Pa. The engineering firm of Mackintosh, Hemphill & Co. of Pittsburgh, Pa., was retained by the Aetna company for the purpose of developing the mechanical apparatus necessary for the large-scale utilization of the process. Mr. C. C. Stutz was placed by this company in direct charge of engineering matters, under the general supervision of Dr. F. L. Slocum, as representative of the Aetna interests.

EXPERIMENTS WITH VARIOUS SIZES OF TUBES

The original apparatus which was used in the laboratory experiments consisted of a tube $1\frac{1}{2}$ in. in diameter by 3 ft. in length. By many steps it was found that a 6-in. by 10-ft. tube was satisfactory and in harmony with those obtained with other tubes. It was proved that the reaction could be carried on as successfully in a tube of this size as in the much smaller tubes which were first used. But it was evident that the maximum size of furnace body had not yet been found, which suggested the advisability of experimenting with a tube of larger capacity, and tubes up to 14 ft. in length were tried.

From this whole series of experiments it was evident that conversion into low-boiling aromatic hydrocarbons will take place in tubes of any size from $1\frac{1}{2}$ in. by 3 ft. to 8 in. by 14 ft.

Reactions occur as readily in one size of tube as another. The variation in extent of heating surface, however, makes it necessary properly to adjust conditions of temperature, pressure and rate of feed in order to obtain maximum conversion and minimum waste in the form of ultimate decomposition products. The desirable combination of conditions must be experimentally determined for each oil used as original material. It was found that for an 8-in. diameter 14 ft. exceeded the optimum length which could be used, because of the mechanical rather than chemical disadvantages. Likewise it was found that a 7-ft. tube was too short, not because of chemical or mechanical difficulties, but on account of the commercial factor of greatly decreased capacity. The most efficient length for tubes 8 in. in diameter was determined to be 10 ft. (for the heated zone).

A long series of experiments was made with a view of using multiple-tube furnaces instead of single tubes.

Observations of the results obtained in a single-tube furnace as compared with those obtained in 10-tube furnaces demonstrated the superiority of the single-tube over the multiple-tube arrangement.

No difficulty was experienced in maintaining temperature control over the single tubes, whereas it was a constant problem to obtain anything like uniformity of heating conditions with the multiple-tube furnace. To get a uniform heat over a small area of the tube it must be heated on more than one side by burners near one plane. This is not possible in the multiple-tube furnace, but is easy of accomplishment in the single-tube type. One side of the tube in the multiple furnace often becomes too hot and the other side too cold. This would not be the case with the smaller installation.

Separate compartments for each tube would, it is believed, be as satisfactory as single-tube furnaces if sufficient combustion space were allowed. The cost of construction would naturally be less if a number of these compartments were constructed as a unit. It is not recommended, however, that more than four such compartments be arranged in a single unit.

Another recommendation in favor of the single tube is the fact that accurate observation of heating conditions is permitted, which is impossible in the multiple type. With the single-tube furnaces a proportionally much larger combustion space can readily be obtained. The larger combustion space will permit a better mixture of the gas and air and will tend to give more uniform heat conditions, owing to the greater distance the products of combustion must travel before reaching the

FIG. 1—PLAN AND ELEVATION OF FURNACE

tubes. An outer combustion chamber in which combustion takes place before the gases enter the furnace chamber in which the single tube is set would enable the brickwork in the interior of the multiple furnaces to be dispensed with without any change in the results.

Independent operation of the tubes would permit a tube to be removed or replaced without interfering with the operation of the other tubes. This is difficult in the case of a nest of tubes in a multiple furnace.

Description of Aetna Plant

The details of the furnace construction of the Aetna plant as finally built are given in Figs. 1 and 2, together with the general dimensions of the furnace. The photographs show various parts of the plant.

The furnace proper consists of an outer shell of common brick, lined with a single thickness of standard firebrick. The over-all dimensions of the 10-tube furnace are approximately as follows: Height 12 ft. 5 in., clearance between top and bottom plates 11 ft.; length of sides 16 ft. 1 1/2 in., clearance between inner walls 13 ft. 10 1/2 in., and width 9 ft. 4 1/2 in., clearance between side walls 7 ft. 1 1/2 in. Twenty-two gas burners are used for heating each furnace. Any common type of gas burner of sufficient capacity may be used. The consumption of gas per tube averages about 300 cu. ft. per hour with the present installation, which has not been operated with particular regard to economic heating.

The interior of the furnace is filled with a checkerwork of firebrick. The gaseous products of combustion

pass through a baffle arrangement from the gas ports, ascend through the checkerwork and are drawn inside the chambers of firebrick in which the tubes are placed. From these chambers the gases pass out through two flues at the bottom of the furnace shell and are discharged into the open air through stacks 18 in. in diameter placed at one end of the furnace. The flues are so arranged that the products of combustion of the eleven burners on one side of the furnace pass out through an individual stack. The brick shell of the furnace is strengthened by five steel buckstays on each side and three on each end, these stays being approximately 15 ft. 8 in. high and 8 in. wide. The tops of the stays are connected with tie-rods so as to give greater stability to the furnace. The burners of the upper row are placed at a height of 3 1/2 ft. above the heater platform. It has been found necessary to have a double set of burners in order to supply the additional heat required to maintain the tubes at the desired temperature.

The furnaces are set at a height of 10 1/2 ft. above the ground, and rest on 16-in. I-beams, supported by 8-in. I-beams. The furnaces were thus elevated because it was necessary to place carbon receptacles immediately under the bottom of the tubes, and to rotate the stirring rod from below. The carbon receptacles and the stirring-rod drive rest on concrete foundations.

OIL-FEEDING EQUIPMENT

The general arrangement of the oil feed to the tubes is shown by Fig. 3, which is a sketch of a furnace and its connections. The oil is pumped to the supply tanks, which feed the five tubes on each side of the furnace

FIG. 2—CROSS-SECTION AA OF FURNACE

and is forced into the tubes by means of triplex pumps, one pump being supplied for each tube.

The oil delivered to each tube by a separate pump traverses a pipe line which is suspended below the upper floor, and thence passes through a needle valve into the top of the tube. The pumps are so constructed that each pump can be calibrated to give any desired rate of flow. The needle valve, which is shown in the foreground, permits independent control of the rate at which the oil is fed into the tube, and enables the oil supply to be immediately cut off in case of accident happening to the tube.

The installation of separate pumps was considered necessary in order to have each tube operated as a

separate unit, notwithstanding the fact that ten tubes were incased in a single furnace.

In the system as installed each tube may be regarded as a separate unit, having no connection with the operation of the other tubes. This type of installation has enabled the reactions occurring in the individual tubes to be carefully studied and has given valuable data which it would be impossible to obtain if the products of all the tubes passed into a single condenser and if a common header were used for supplying oil to all of the tubes.

The individual pumps have served their purpose, but it is not recommended that such a system be used in a new installation. The piping system was so arranged that when the pressure in the tube exceeded the predetermined mark the oil delivered by the pump would be by-passed back into the feed tank.

At first oil meters for measuring the supply fed to each tube were not used, but it was found that the amounts of oil fed into the different tubes varied widely.

The use of meters has been adopted in order to determine accurately the amount of oil passing into the individual tubes, a meter being installed in each feed line. It has been found that through the use of meters better control and regulation of temperature can be obtained than would be otherwise possible, as the rate of feed can be accurately adjusted to conditions existing in the furnace. It is recommended that oil meters be used in any new installation, as the individual cost of

the meters is small (approximately \$8 each) and the benefits obtained are more than commensurate.

APPARATUS FOR REMOVING DEPOSITED CARBON

The most serious problem that was faced at the outset of operations was the removal of carbon formed on the walls of the tubes. Carbon incrusting on the tube walls acts as an insulator and interferes seriously with the transmission of heat from the furnace to the vaporized oil; also the gradual accretion of carbon diminishes the size of the reaction chamber until the tube becomes entirely choked, which necessitates shutting down the furnace to remove the deposit.

The use of cracking chambers of so large an internal diameter as 8 in. introduces another factor which makes it desirable to use stirrers. In order to heat gases in

CHARACTER OF CARBON FORMED IN OPERATION OF BENZENE-TOLUENE PROCESS. THIS IS THE CHARACTER OF COKE THAT RETARDED OPERATIONS IN THE EARLY STAGES OF DEVELOPMENT OF THE PROCESS

FIG. 3—DIAGRAM OF FURNACE CONNECTIONS

TAR NECKS AND CARBON POTS, SHOWING ALSO ARRANGEMENT OF GATE VALVES

the axis of an 8-in. cylinder to any desired temperature a considerably higher temperature must be maintained at the periphery of the cylinder. One of the advantages of the use of the stirring rod is, therefore, that it makes the cracking chamber annular. Also the stirring action of the rods and chains tends to promote transverse circulation of the gases, which helps to equalize the temperatures.

The use of stirring rods was decided on after careful weighing of the probable advantages of a number of possible devices.

It is apparent that if the rods are continuously rotated in a given direction no means is afforded for cleaning the rod and the chain attached thereto, so that carbon will collect until the accumulation extends to the wall of the tube. The presence of carbon on the surface of the rods and on the chain itself does not, however, interfere with the operation of the apparatus until the amount becomes sufficient to impede the movement of gases through the chamber. When this point is reached the flow of oil into the tube must be stopped and the rod removed and cleaned.

At the outset a rod could be operated only 10 to 24 hr., when the amount of carbon deposition would compel its removal. It has been found possible to increase the length of service to anywhere from 7 to 10 days, with occasional runs of even longer duration.

The use of a rotating rod with wiping chains attached has demonstrated that it will keep the walls of the tubes free from carbon. With the improvements in the construction of this rod which experience has shown to be advisable, and with uniform heat control, it is believed that this type of cleaner can be used with satisfactory results. The great objection, however, to any cleaning device which is permanently retained in the cracking chamber is the fact that although it can be made to clean the walls of the tube there are no means for cleaning it. It is only a question of time, therefore, which in this case means days, before the amount of carbon built up is such as to necessitate the removal and cleaning of the device. Therefore, from a purely mechanical standpoint, a type of cleaner which is not to be permanently retained in the reaction chamber would be more satisfactory, if it cleaned the walls of the chamber equally well. It is entirely possible that a type of plunger cleaner will be found to accomplish this result and obviate the fundamental objection to the use of any intermittent cleaning device, which is the difficulty in obtaining a continuous oil feed and main-

taining uniform conditions of operation. But a plunger cleaner head would be more costly to install and would necessitate detachment whenever a tube was to be removed or its condition examined. Likewise the advantages that accrue from throwing the gases against the walls of the tube would, of course, be largely lost with plungers.

CARBON POTS AND TAR NECKS

The tar neck, so-called, is attached to the bottom of the tube by a flanged head, which is bolted to the corresponding flange attached to the tube. The fixed and the condensable gases, and the carbon which has been removed from the walls of the tube by the mechanical stirrer, pass downward into the tar neck or chamber.

A baffle wall or curtain in the upper part of the chamber around and below which the gases must pass, in order to enter the vapor line leading to the condenser, tends to prevent a large percentage of free carbon from being mechanically carried over with the gases into the condenser. The greater specific gravity of the carbon and pitch causes them to settle rapidly to the bottom of the chamber. (See Fig. 3, p. 273.)

A fan is attached to the vertical shaft which engages with the stirring rod, and is continuously rotated during the progress of a run in order to keep the stirring-rod bearings from being clogged. The action of the fan has a slight tendency also to draw the gases down from the reaction chamber and into the tar neck. The gases, however, being lighter than the heavy pitch and carbon formed, will rise and pass out through the vapor line, leaving the heavy tars and carbon behind.

Carbon receptacles such as those here depicted have the disadvantage of limited capacity. It has been the practice to release the pressure from the tube and to suspend operations while the carbon and pitch were being removed from the carbon receptacle. The duration of the run was fixed accordingly by the capacity of the carbon pot.

The results of the large-scale operations have shown that such massive equipment is not essential. However, this fact could not be predetermined, and it is to the credit of those responsible for the installation that safety has been the first consideration throughout the entire process of development.

The change in the character of carbon formed in the tube from a dense hard coke to a soft flaky carbon, or a heavy viscous tar, has also tended to make the use of large castings unnecessary in the future. If a clean

ENLARGED CARBON POTS USED IN NEWER TYPE OF INSTALLATION

oil is used, such as the distillate to which frequent reference has been made, there is every reason to believe that in place of individual carbon receptacles the tar and carbon can be run from the tar neck direct into a common header and discharged from there into a suitable receiving tank. In fact, provision to this end is now being made at the development plant. If the residuum of recovered oil above the 175 deg. C. cut, or the liquid product from the condenser, is pumped through a suitable opening in the tar neck, there should be no difficulty in causing the carbon and pitch to flow freely through the header. The oil so used can be recovered readily.

The soft flaky carbon is the kind that is formed when proper tube temperatures are maintained throughout a run on Oklahoma crude oil. This soft carbon is usually accompanied by a heavy tar sludge, which is not generally as viscous as that shown in the illustration. Coke is formed when excessive furnace heating occurs. With careful regulation of burners very little of this coke will be produced. The carbon constitutes a valuable by-product and is adapted to a wide variety of industrial uses. It is worth from 1 cent per pound upward, depending on its condition and relative freedom from metallic oxides.

CONDENSERS

At the outset of the experiments it was felt desirable, as previously mentioned, to have each tube operated as a separate unit, thus making it a complete system in itself. This necessitated the use of an individual condenser for each tube. If this plan had not been followed a study of the conversion results in the separate tubes of a single furnace would have been out of the question.

In all new processes a great deal of the equipment considered necessary at the outset can be dispensed

with subsequently. This is the case with the individual condensers. Fig. 4 gives details of the condenser construction.

The gases are carried to the condenser through a 3-in. pipe some 12 ft. in length. A receptacle termed the primary separator is connected with the vapor line, in which the more readily condensable liquids are collected. The gases which remain uncondensed at this point pass upward through a 3-in. U-shaped iron pipe into a twin water-cooled condenser consisting of 3-in. copper pipes incased in iron pipes through which water is continually circulated. The liquids which are condensed pass by gravity into what is called the secondary separator. The fixed and uncondensed gases are discharged into a gas header on the upper floor of the furnace building by means of a 1½-in. pipe whenever the pressure on the system exceeds the predetermined pressure.

The primary separator is 8½ in. in diameter by 3 ft. 4 in. in height. The secondary separator is 10½ in. in diameter by 5 ft. 6¼ in. in height. These separators hold as much liquid as will be condensed during a run of the duration permitted by the capacity of the carbon receptacle.

The twin water-cooled condensers are approximately 7 ft. 10 in. in height and have an internal-wall area of approximately 10 sq. ft.

The inefficiency of the condensers, which led to the installation of a large-size condenser and gas scrubber, is shown by the amount of aromatic hydrocarbons in the oil immediately on leaving the condenser and the amount in the same oil after it had been exposed to the air in open barrels, in which it was customary to store it temporarily. It was found that between 30 and 50 per cent of the low-boiling aromatic hydrocarbons formed in the tube had evaporated while the oil was allowed to stand in contact with the air. Some liquid was mechanically carried over by the gases and did not condense in the individual condensers.

The volume of gas formed in the cracking process is

ARRANGEMENT OF CONDENSERS FOR MULTIPLE-TUBE FURNACES

FIG. 4—DETAILS OF CONDENSER CONSTRUCTION

so great that a very considerable percentage of both light and heavy oils is mechanically carried over and does not yield readily to condensation. Traps were placed in the gas line, into which the uncondensed gases were discharged, and analyses have been made for a number of different runs. It was found on distillation from the traps that 50 to 60 per cent boiled over below 175 deg. C., in which cut the benzene content ranged from 5 to 21 per cent and the toluene content from 8 to 25 per cent.

In any new installation for the employment of this process, provision should be made for a condenser of the same type as that used in oil refineries. With the benzene-toluene process, the condensation problem is, however, markedly different from that of the refinery where all the vapors coming from the still are condensable, as in making benzene and toluene considerable volumes of fixed or noncondensable gases are generated. In general a condensing area of approximately $2\frac{1}{2}$ ft. for each barrel of original oil used per day will be found satisfactory if a gas scrubber is operated in connection therewith. This gas scrubber can be modeled after the benzene scrubbing towers in by-product coke-oven plants, or may consist merely of a large tank filled with a heavy oil through which the gases are bubbled. This tank should be so inclosed that the fixed gases can be conducted to a gas holder for the purpose of supplying fuel for the furnaces, if desired. In by-product coke-oven practice the introduction of back pressure by forcing gas through a body of oil would seriously affect the coking products, whereas in the process herein described there is sufficient direct pressure to work against any desired head of oil.

GENERAL DESCRIPTION OF CRACKING SYSTEM IN COMMERCIAL PLANT

The cracking system, both in the benzene-toluene and gasoline processes, is a closed one. Pressure is maintained throughout the entire system while operations are being carried on. The component parts of the system are shown in Fig. 3, in which the various parts are labeled.

The oil is delivered by the pump through the feed line passing under the upper floor, and is carried into the tops of the tubes at a predetermined rate of feed. In the benzene-toluene process the rate of feed is approximately 15 gal. per tube per hour. This rate would be more than doubled in the gasoline process for tubes of the same size. Only a very small quantity of oil is present in the tube in a gaseous form in a given period of time, as a rate of 15 gal. per hour is equivalent to the delivery of only 1 quart of oil per minute. If the oil is preheated, a much higher rate of feed can be attained in both processes.

The oil, upon entering the top of the tube, is spread out over the surface of the basket, which consists of a cast-iron pipe with a perforated top. In the laboratory experiments a basket filled with steel balls was used. These balls were also used in the furnace containing a battery of ten $4\frac{1}{2}$ -in. tubes. It was found, however, that the same results could be obtained by dispensing with the obstructing material and using a spreader of the type mentioned.

The pumps are so set as to deliver the oil under a pressure greater than that in the tubes, so that no difficulty is experienced in causing the oil to flow into the tubes regardless of the pressure employed. The hydrocarbon material fed in is flashed or instantaneously transformed into a gaseous condition and passes downward through what is termed the "cracking zone" of the tube proper, where a temperature is maintained higher than that in the gasification zone. It is in this

part of the container that the heavy hydrocarbons are broken up under the influence of temperature and pressure and in the presence of hydrogen and fixed hydrocarbon gases. Most of the cracking occurs in this zone, although there may be some cracking immediately below the point of gasification. Although not absolutely necessary, it has been found preferable to effect gasification at a point above the cracking zone.

The condensable gases, which are the desired conversion products, pass out of the tube through the tar neck and enter the vapor line leading to the condenser. The gases which remain uncondensed ascend through the gas line connected with the top of the secondary separator and are discharged through pressure release valves either into the open air or into the gas header. The release valve discharging into the open air is used so that in case of any difficulty arising the pressure can be released in the minimum space of time.

The process, however, is not limited to the use of petroleum products, but can be efficiently operated on liquid hydrocarbon material derived from any source. Solvent naphthas, and light oil distillates from water-gas tars and coal tar have been successfully used. These light oils and solvent naphthas are extremely favorable for use in the process as yields two to three times larger than those obtainable from petroleum products can be had in a single operation. The petroleum oils, however, give a wider range of by-products. This fact, together with their greater availability, as well as lower cost, probably render them most suitable for use. Wherever supplies of the distillates from coal or water-gas tar are available in quantity, they are a most prolific source of benzene and toluene. If such distillates were procurable in the open market their use would be highly profitable at a time like the present (1915), when both benzene and toluene are commanding heretofore unheard-of prices.

The great advantage in the use of light-oil distillates from coal and water-gas tars, aside from the greater yields obtainable, is the fact that diminished pressure can be used. Vacuum or atmospheric pressure has been shown to give results as favorable with these oils as higher pressures.

The experiments have clearly indicated that the vapor-phase cracking process is not limited to any particular type of oil, and that an asphaltic oil, a paraffin-base oil, oil having a paraffin and asphaltic base, and certain oils obtainable from the destructive distillation of coal, are all suitable for use in the process.

The combustion chamber in the multiple-tube furnace contains approximately 1100 cu. ft. of space or an average of 110 cu. ft. per tube. This combustion volume seems to be insufficient for the best results under the conditions of operation which have existed during the period covered by this report. It is believed, however, that much better results could be obtained with this volume of furnace per tube if it were to be combined with an efficient outer combustion chamber.

In the operation of the plant a laborer, termed a heater, is employed for each furnace of ten tubes. This man has charge of the 22 burners required to heat a single furnace, and is engaged constantly in the regulation of the burners in order to maintain the required temperature. This regulation of heat is controlled by optical determination of the temperature, as judged by the condition of the tube and brickwork in the interior of the furnace. Pyrometers have also been used, but have given results of varying character.

Pressure in the cracking system is maintained by controlling the discharge of the gases formed by the decomposition of the hydrocarbons fed into the tube. In the operation of the process at the development plant

a laborer is employed for each unit of five tubes in order to regulate the pressure. Regulation is accomplished by opening a valve and permitting the gases to escape into a gas main or header until the pressure in the individual tube has been sufficiently lowered to keep it at the point required.

When as large a quantity of benzene as possible is desired the pressure used was 250 lb. per square inch. When it was desired to obtain more toluene a pressure of 150 lb. was used.

As was stated in the discussion of temperature, carbon difficulties increase when heat is not uniformly regulated. The experiments again indicated the already well-known fact that the percentage of carbon formed increases with temperature.

The presence of carbon in the reaction chamber is a disadvantage from the mechanical side alone. From various references in the appended bibliography it can be discovered that carbon is one of the best catalysts for the formation of benzene and toluene.

It is evident from the development of the process that formation of carbon in the cracking tube is not an obstacle to the operation of the process when control conditions are in proper relationship. Too low a rate of feed at a moderately high temperature will cause higher percentages of carbon to form. Excessive temperatures and pressures will likewise promote excessive carbon formation, but when these factors are in their proper relationship the character of the carbon is such that little or no difficulty is encountered in its removal.

Plain lap-welded tubes have not proven entirely satisfactory. A small number of lap-welded tubes that were calorized (coated with aluminium) by the General Electric Company have been in operation for several weeks. The results to date of writing have been entirely satisfactory, especially as less carbon trouble has been experienced with these tubes than with like tubes not calorized.

Based upon experience extending over a period of seven months, it is recommended that either rolled or cast steel tubes be used in lieu of lap-welded tubes. The walls of the tubes should be not less than 1 in. thick for maximum efficiency in operation.

The benzene-toluene process produces more than enough gas for continual operation of the cracking furnaces. Regardless of the character of oil used, 40 to 50 cu. ft. of fixed gases is generated for each gallon of oil cracked.

Very small amounts of gas are produced in the gasoline process as compared with the benzene-toluene process, consequently either natural gas, oil, or some other form of fuel would have to be employed to heat the cracking furnace.

Up to the time of writing no opportunity has been afforded for the detailed study of that part of the recovered oil distilling above 175 deg. C.

It is difficult to give cost data for a unit plant for either the gasoline or benzene-toluene process. Although several plants are being projected for 1916, only one plant has been constructed during the period for which data have been given. This installation is the one owned and operated by the Aetna company. The conditions under which this plant was erected were such as to make the costs unusually high. Consequently it would not be fair either to the company or to the process to quote such figures. Also their quotation is inadvisable.

The cost of a gasoline plant will be considerably less than that of a benzene-toluene plant, as little or no carbon is formed and elaborate equipment for the removal and reception of this substance is not required; also a gas scrubber and a gas holder would not be needed, as

the volume of fixed gases generated in making gasoline is small.

Large-Scale Gasoline Production

Opportunity has not been afforded for testing the gasoline process on a large commercial scale, as is the case of the benzene-toluene process. The inability of the Department of the Interior to accede to the requests made for exclusive rights, or for recoupment of expenses incurred in the development of the gasoline process, has prevented reaching an understanding. At the time of writing licenses have been issued to four refining companies, each of which is about to install small experimental units.

The Aetna Explosives Co. has been most courteous and obliging in extending facilities for conducting gasoline tests in the single-tube furnaces, during such times as the use of the furnaces could be spared for this purpose. Accordingly a considerable number of runs were made in the single tubes with the different oils available. Three oils were used in the experiments, one was a fuel oil from Pennsylvania-West Virginia crude petroleum and the other two were distillate oils, one having a boiling point ranging between 250 deg. and 350 deg. C., and the other between 200 deg. and 300 deg. C.

Experiments were made with a 6-in. by 9-ft. tube and with an 8-in. by 10-ft. tube. The average percentages of gasoline recovered were low, being 18.8 per cent and 21.5 per cent with the 6-in. by 9-ft. tubes using two distillate oils and 19.5 per cent with the 8-in. by 10-ft. tube using distillate oil. An average recovery of 24.3 was obtained with a distillate fuel oil in the 8-in. by 10-ft. tube but the average percentage of recovered oil was lower.

In considering the figures obtained, it must be remembered that efficient condensation was lacking. The work was carried on during intervals when benzene-toluene experiments were being conducted with equipment erected to obtain indications as to benzene-toluene reactions, and not to determine maximum yields. Accordingly the condensing facilities were of the crudest type. The results can be considered only as suggestive of what can be accomplished under proper conditions. Viewed in this light they are of a distinctly favorable character, and justify optimistic belief in the large-scale commercial possibilities of the process.

GASOLINE PROCESS COMPARED WITH BENZENE-TOLUENE PROCESS

In comparison with the benzene-toluene process, the gasoline process is simple in character. This may be more readily perceived by considering the order of hydrocarbon reactions as given below. The relative order is not only based on theory, but is in accordance with the evidence gained as the result of extended series of tests.

The order of the reactions is as follows: heavy petroleum hydrocarbons $\rightleftharpoons$ light petroleum hydrocarbons (saturated and unsaturated) $\rightleftharpoons$ cymene $\rightleftharpoons$ xylene $\rightleftharpoons$ toluene $\rightleftharpoons$ benzene $\rightleftharpoons$ naphthalene, diphenyl, etc., $\rightleftharpoons$ anthracene, $\rightleftharpoons$ carbon and gas.

The conversion from heavy hydrocarbons into lighter hydrocarbons involves only one step, and is easy of accomplishment, whereas the conversion into the lower boiling aromatic hydrocarbons requires that the heavier hydrocarbon molecules undergo a much more extensive series of changes before the desired products are obtained. This difference will indicate why the mechanical difficulties experienced in the first stages of development of the benzene-toluene process are non-existent so far as the gasoline process is concerned. The lower

temperatures necessary and the greatly decreased quantity of carbon produced eliminate serious trouble from overheating and clogging in gasoline manufacture.

Because of the greater ease with which gasoline can be made the installation used for benzene-toluene production will have double the capacity when used for conversion of heavy oil into gasoline. The duration of the gasoline reaction is less than half that required for the benzene-toluene reaction if the same size and length of tubes be used. It is manifest, therefore, that by introducing twice the volume of oil to be converted, the effect will be the same as decreasing the time factor by one-half.

The installation if used solely for gasoline production can be materially changed in many respects. The expensive carbon receptacles can be done away with, and the height of the furnaces above the ground materially reduced, thus lowering the cost of furnace construction.

The large-scale experiments have fully confirmed the laboratory experiments and established the fact that the conversion into gasoline can be even more satisfactorily accomplished in a tube of greatly enlarged diameter and increased length than in the electrically heated 1½-in. tube. The conditions favorable for gasoline production are shown to be the same in the larger tubes as in the small tube, namely, a temperature of approximately 500 deg. to 575 deg. C. and a pressure of 250 to 300 lb. per square inch.

The gasoline process, therefore, can justly be considered as a success so far as conversion in the large tubes is concerned. The adaptation of the unit to refinery conditions is a matter of mechanical detail involving no inherent difficulties.

Early in September, 1915, the Department of the Interior was advised by the Aetna Explosives Co. that the plants were completed for the production of explosives from benzene and toluene obtained by the process of cracking in the vapor phase. In accordance with the express understanding between the company and the bureau, this necessitated the severance of the co-operative relations existing. This understanding was had to obviate any objection due to the utilization of Government employees in work involving the preparation of explosives.

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver

Metallurgy of Native Silver Ores of Mexico.—In a paper presented at the second Pan-American Scientific Congress, Washington, D. C., Mr. W. M. BRODIE discusses the treatment of native silver ores occurring in Chihuahua, Mexico. Ores of this type were worked at Batopilas before 1632, by methods of sorting and cobbing together with smelting in crude forms of reverberatory and blast furnaces. At the present time the silver is recovered by concentration, amalgamation, cyanidation and smelting. The enriching of the ore begins in the mine, where pains are taken to separate high and low-grade material.

The high-grade ore is fed by hand to stamps, the fine passing the screen and the coarse remaining in the mortar. The latter is removed and washed by hand, after which it is ready for refining. The stamp discharge which has passed a 30-mesh screen, is treated in amalgamation pans with 0.5 per cent cyanide solution, and as soon as the grinding is completed mercury is added to collect the metallic silver. The pan tailing is discharged to a settler and thence to a Dorr thickener and Pachuca agitator, being treated in the last machine with 0.5 per cent cyanide solution. The amalgam, which

may contain from one-third to one-half silver, receives the usual treatment, and the retort silver runs about 950 fine.

Low-grade ore assays from 10 to 20 oz. silver per ton, depending on its proximity to high-grade deposits in the mine, but is usually of 10-oz. grade. This is concentrated on tables of the Bartlett and Wilfley types, the tailings containing about 2 oz. silver per ton. The concentrates are re-concentrated and separated into two grades, one containing 3000 to 7000 oz. per ton and the other from 200 to 400 oz. A third-class concentrate of about 100 oz. may be obtained, and the tailing usually carries between 8 and 9 oz. per ton. The ratio of concentration is about 50:1.

The first-class concentrate is treated in an amalgamating pan with cyanide solution and mercury, and is reduced in value to about 30 oz. per ton. It is then added to the other pan tailings in the Dorr thickener. The second-class concentrate is cyanided by percolation together with the coarse settlings from the settlers in which the pan tailings are washed after amalgamation. The silver leaches slowly but without difficulty.

The silver is precipitated on zinc shavings in the usual manner, and the precipitate is filtered and dried in a cast-iron retort. It is then refined together with the stamp-mill silver and the pan silver in a reverberatory furnace of the Freiberg type. The pan and stamp-mill silver are charged first, and when the contained silica floats on the charge, the cyanide precipitate mixed with about 5 per cent borax glass is added. In this way a fairly fusible slag is made and skimmed. If the bath is kept at the proper temperature there is no great loss of silver by volatilization.

Slags from refining are ground and sifted to recover metallic silver, which is then treated in an amalgamating pan with cyanide solution and mercury in a manner similar to that used for high-grade concentrates. This avoids by-products and cleans up the operation quickly.

Copper

Leaching at Chuquicamata, Chile.—The metallurgical methods employed by the Chile Exploration Company in treating the copper ores at Chuquicamata, Chile, were outlined in detail in this journal May, 1914. Since that time the proposed methods have been put in successful operation, and some data from practice are given by Mr. C. A. ROSE in a paper presented at the second Pan-American Scientific Congress, from which we abstract the following:

The ore is leached in 10,000-ton concrete vats, and the first solution is applied by upward percolation in order to avoid an accumulation of fine ore at the bottom of the vat. This solution is allowed a contact of from thirty-six to forty-eight hours, when it is withdrawn and replaced with solution acting by downward percolation. The following extract from a report sheet will show the cycle of treatment:

LEACHING OPERATION SHEET									
Charge No. 41 Tank No. 5		Date charged, Oct. 9, 1915 Tonnage, 8,212 met. tons							
Date	Solutions Put on				Solutions Drawn off				
	Cu.	M.	Copper	Grams per Liter Acid Chlorine	Cu.	M.	Copper	Grams per Liter Acid Chlorine	
13	3.300	34.8	68.0	1.9					
17	2.560	21.7	69.5	0.7	2.700	47.8	38.0	4.9	
18	2.050	25.0	50.4	0.6	2.320	42.1	52.0	3.0	
	3.275	36.4	43.6	2.8	3.312	36.3	48.0	2.1	
	3.225	30.7	32.8	2.8	3.312	35.4	43.1	2.5	
	3.375	21.6	19.6	2.4	3.275	30.9	32.8	2.6	
	3.287	7.9	6.4	1.0	3.300	22.1	19.1	2.3	
	Water 600 tons				2.800	11.2	7.5	1.1	

A part of the last solution withdrawn in each cycle is removed for complete deposition of copper, after which it is discarded. The solution thus removed compensates for the increase in volume due to the addition

of more water in the last wash than is discharged as moisture in the residue, and also removes continuously certain impurities that otherwise would accumulate in the solution. These impurities consist of sulphates of sodium, potassium and magnesium, which are in no way detrimental to the process. They accumulate until the circulating solution contains about 150 grams per liter of sodium sulphate, 10 grams potassium sulphate and 65 grams magnesium sulphate, after which the discarded solution removes the same quantity at each cycle as is introduced by the ore. Iron sulphate does not accumulate rapidly, amounting to only 3.4 grams per liter after treating forty-five charges of ore. Some nitric acid exists in the ore, due probably to nitrates blown from adjacent nitrate beds. This acid is prevented from accumulating by the discard of solution. Chlorine is removed in the dechloridizing plant, where the solution is passed through tube-mills containing granulated copper. This precipitates cuprous chloride, which is separated by filtration. Various methods of treating this cuprous chloride have been tried—by smelting, electrolysis and cementation. The last process is indicated as the most suitable, due to the need of securing cement copper for the dechloridizing tube-mills. The method of treatment is dissolution in brine and precipitation on scrap iron. The consumption of iron is less than half that usually found in treating copper solutions, since the copper is in the cuprous state and practically no free acid is present.

Magnetite anodes were first used for electrolytic precipitation, but owing to the impossibility of securing these from Europe on account of the war, duriron has been substituted with success. This material is a silicon-iron alloy, and while not wholly unacted upon by the solutions, from fifteen to twenty times its weight of copper can be deposited before the anode is entirely corroded. Duriron anodes have an advantage over magnetite in their mechanical strength, but a disadvantage in requiring about 15 per cent more electrical energy for the deposition of the same quantity of copper. The purity of Chuquicamata copper is somewhat higher than that derived from American electrolytic refineries; its conductivity is from 100.5 to 101 per cent, Matthiessen's standard.

Metallurgical Methods of the Braden Copper Co.—Two recent publications give interesting data on copper concentrating and smelting at Sewell, Chile, the scene of operations of the Braden Copper Company. In a paper presented before the second Pan-American Scientific Congress, Messrs. R. E. DOUGLASS and B. T. COLLEY, respectively concentrator and smelter superintendent, describe the development of the entire plant at Sewell. Until the advent of flotation, concentration was effected by the usual gravity methods, using Harz jigs, tables and buddles. The recovery of copper in concentrate was not high, and even after an improvement to the original plant it remained low. Minerals Separation flotation process was installed and has resulted in greatly increasing the saving. Originally the froth from the tailing compartments of the machines was retreated in another plant, but this method has been superseded by returning the free-running froth from the last compartments to the head of the same machine. The tailings from Minerals Separation machines are treated by air cells, both rougher and cleaner types.

The reagents used in flotation are Swedish or American pine-tar oil, fuel oil, sulphuric acid and a small amount of kerosene to thin the fuel oil. A part of the pine-tar oil is added at the Hardinge mills and the balance at the head of the flotation machines. A sulphuric acid plant is operated intermittently as needed.

The first smelting plant consisted of agglomerating

or sintering apparatus and a small blast furnace. Owing to excessive loss of sulphur in the sintering operation, the large percentage of fine ore and high operating cost the agglomerating process was not a success. In the second smelting plant the concentrates were briquetted and smelted in a blast furnace, since local conditions made the use of the customary reverberatory inadvisable. There was no difficulty in briquetting the concentrates by the addition of clay, but the concentrate was already high in silica and alumina and called for extraneous flux to form a slag. Limestone was scarce and cost \$12 per ton. The components of the charge were briquet concentrate, converter slag and limestone. The converter slag was easily fused and the sulphides in the briquets quickly melted and separated themselves from the gangue, leaving in the furnace a difficultly fusible skeleton of silica and alumina. Later the flotation plant began operations and imposed a new set of conditions on the furnaces. The flotation concentrates were very fine and easily fusible, but being excessively wet they blanketed the charge and greatly increased the coke consumption. In order to improve these conditions further experiments in down-draft sintering were initiated and a good product was finally made. Still later experiments showed the feasibility of nodulizing the concentrates, all kinds of the latter being treated. The result was the adoption of nodulizing kilns, advantage being found to lie in long kilns of large diameter. The latest type is 100 ft. long and 9 ft. diameter. The smelting of nodules has proved successful and in accord with usual blast-furnace practice, and the fuel consumption dropped to 8 per cent per ton of charge.

In the company's monthly publication, *Teniente Topics*, the following data are given relative to smelting: The concentrate contains 19 per cent copper, 17 per cent silica, 23 per cent iron, 2 per cent lime, 8 per cent alumina and 28 per cent sulphur. Of 350 tons of this material, recovered from 4000 tons of ore, about 215 tons is nodulized, 50 tons is sintered on grates, and 85 tons is smelted raw. The matta resulting from smelting the mixture of nodulized, sintered and raw concentrates contains about 45 per cent copper, and is converted in Pierce-Smith basic-lined converters.

Lead and Zinc

Preferential Flotation of Galena and Blende.—The Australian *Mining and Engineering Review* gives a description of the separation of galena and blende at the works of the Sulphide Corporation, Broken Hill. In this plant the Minerals Separation machines have been superseded by the Hebbard-Harvey under-drive machines, and the capacity is about 4000 tons per week. The flotation plant handles tailings from the lead mill, where the largest part of the galena is separated. These tailings carry 4.2 per cent lead and 18 per cent zinc. The pulp is first agitated with eucalyptus oil, and the froth carries 57 per cent Pb. The residue assays 3 per cent Pb and 18.5 per cent Zn. In the next flotation treatment oil and acid are used, and the concentrate assays 6 per cent Pb and 47.5 per cent Zn. The final tailing assays 1 per cent Pb and 2 per cent Zn. The process is conducted in the cold and effects the recovery of an additional 15 per cent lead and silver as compared with the process previously in use. Another important factor in this separation is that the new process may permit the fine tabling in the lead mill to be discontinued. Rhodonite forms the principal obstacle to successful tabling, as its specific gravity is between that of galena and blende. Flotation, however, gets rid of rhodonite as well as of other gangue matter, and makes possible an easier separation of the two minerals in subsequent tabling operations.

Iron and Steel

Vacuum-Fused Silicon-Iron.—In a paper in the February issue of the *Bulletin* of the American Institute of Mining Engineers, T. D. YENSEN of the University of Illinois, gives the results of his experiments on vacuum-fused iron containing varying percentages of silicon. The experiments were made in an attempt to improve the iron used in dynamo-electrical machinery. The qualities desired were low hysteresis loss, high electrical resistivity (to reduce eddy-current loss), and high permeability. Previous experiments by the author had shown that pure electrolytic iron, melted and cooled in vacuo, possessed desirable properties in respect to high permeability (about twice that of the best commercial iron) and low hysteresis loss. If the electrical resistivity of this iron, which in the pure state is very low, could be increased without impairing its magnetic properties, an excellent iron for electromagnetic purposes would be produced. Previous experiments by Prof. C. F. Burgess at the University of Wisconsin had shown that when melted in an atmosphere of carbon monoxide at ordinary pressures pure iron absorbed about 0.1 per cent carbon and probably some oxygen as the electric resistance increased more than would be expected from the carbon alone. The iron used in the present experiments was doubly refined electrolytic iron deposited from Swedish charcoal iron according to the methods of Burgess (see this journal, Vol. II, May, 1904). The refined iron had the following composition: carbon, 0.006 to 0.01 per cent; silicon, 0.01 per cent; sulphur, trace; iron (by difference), 99.98 per cent.

The experiments were made in a vacuum furnace modeled after the Arsem type (see this journal, Vol. IV, page 223, June, 1906), and a Geryck pump was used capable of maintaining a pressure of 0.5 mm. of mercury or less with 500 grams of molten iron in the furnace. Previous experiments by the author had shown that carbon and boron when alloyed with this vacuum-fused iron lowered the magnetic quality and they were thus undesirable where high permeability and low hysteresis were needed. The present experiments with silicon gave opposite results and seem to have produced an iron which possesses very remarkable properties highly desirable in iron for electrical machinery. Before being used the iron was crushed, cleaned with hydrochloric acid, water and alcohol and dried by means of ether in vacuo. About 600 grams of this cleaned iron was then placed in a fused magnesia crucible together with the desired portion of the alloying element, covered with a magnesia cover and placed in the vacuum furnace where it was melted under a finishing pressure of 0.5 mm. of mercury. The ingots, after being allowed to cool in the furnace, were heated in an ordinary coke forge and forged into rods about $\frac{1}{2}$ in. (1.25 cm.) by 20 in. (50 cm.) under a steam hammer. No contamination took place in this operation. From these rods the test pieces were prepared; one rod 14 in. (35.5 cm.) long for the magnetic and electrical tests; two test pieces, $2\frac{1}{2}$ in. (6.3 cm.) long, with threaded ends, for mechanical tests; and one small specimen for the metallographic investigation. Magnetic and electrical tests were made and photomicrographs were taken after the following heat treatments:

- As forged.
- Annealed at 900 deg. C. Cooled at a rate of 30 deg. per hour.
- Annealed at 1100 deg. C. Cooled at a rate of 30 deg. per hour.

Mechanical tests were made as forged and after annealing at 970 deg. C. A few specimens were annealed at 1100 deg. C. The annealing was done in vacuo so as to preclude any possible contamination by gases, the

vacuum part of the furnace used for this purpose consisting of an "electroquartz" tube with mercury-sealed ends.

The results are summarized as follows:

By means of the vacuum method of melting it is possible to obtain a decidedly purer product than has thus far been obtained in any other manner. Consequently by the use of this method more definite conclusions than have hitherto been possible can be drawn with regard to the effect of silicon upon iron.

Silicon, like boron, has a double effect upon iron. Part of it combines with the iron and remains in solid solution throughout the cooling of the alloy, while a smaller part reduces the iron oxide present.

The tensile strength of the vacuum product follows in general the same law as alloys made under ordinary conditions, but the ductility of the former is much greater, particularly below 2 per cent and above 3 per cent, probably due to the absence of carbon. The maximum tensile strength of 105,000 lb. per square inch (73.5 kg. per square millimeter) occurs with a silicon content of 4.5 per cent.

The limit of forgeability lies between 7 and 8 per cent silicon. A critical range occurs between 2.50 and 2.60 per cent, in which the alloys are exceedingly brittle, in some cases being not even forgeable. The chemical composition of the latter corresponds to a compound of the formula Fe_2Si .

With regard to the magnetic properties, the vacuum alloys exhibit most remarkable characteristics. The best alloys are obtained with about 0.15 per cent, and 3.40 per cent silicon after annealing at 1100 deg. C. The maximum permeability for both of these alloys is above 50,000, and the hysteresis loss for $B_{\text{max}} = 10,000$ and 15,000 is about 300 and 1000 ergs per cubic centimeter per cycle respectively. This hysteresis loss is 1.8 and $\frac{1}{3}$ of the corresponding loss for commercial silicon steel. The most favorable annealing temperature is in every case 1100 deg. C.

The specific electrical resistance increases about 13 microhms for the first per cent silicon added. For each additional per cent added the increase is about 11 microhms. Consequently the 3.40 per cent alloy mentioned above has a resistance nearly five times that of the 0.15 per cent alloy.

By the vacuum process two silicon alloys have thus been produced that have very valuable characteristics; one low in silicon, not very strong, but extremely ductile, of high permeability, low hysteresis loss, and of low electrical resistance; the other high in silicon, very strong, moderately tough, of high permeability, low hysteresis loss and of high electrical resistance. The properties for these two alloys are summarized in Table I. The first is evidently suitable for use in places where high permeability and low hysteresis loss are the chief requirements, while the second alloy is suitable for electromagnetic machinery, principally transformers, where a low eddy current loss is an additional requirement.

Recent Chemical and Metallurgical Patents

Iron and Steel

Regenerative Furnace.—A regenerative furnace for open-hearth steel practice, which uses pulverized coal, forced draft, and may be placed above the open-hearth furnace proper and within the same walls, is patented by JOHN E. BELL of New York City. The arrangement of the regenerator is shown in Fig. 1. Air is blown in through 7 from a blower, and passes through the successive parts of the right-hand generator, *a*, *b*, *c*, and *d*, respectively, when the valve is arranged as in the drawing. At the same time pulverized coal is fed in at 17*a*, in separate combustion chamber 5*a*. The falling coal and preheated air unite and the coal burns forming a producer gas, which passes under 14*a* and up through 3*a* to the hearth of the furnace 2. The ash of the coal falls on grate 15*a* where steam or steam and air is introduced to aid in consuming any unburned

FIG. 1—REGENERATIVE FURNACE

carbon and prevent the formation of clinker. The gases pass out at 3 and up through chamber 5, to second regenerator 4, and thence through 8 to the stacks. When reversed the coal is stopped at 17*a* and is fed in at 17 in the other side.

A secondary combustion may be effected by introducing auxiliary heated air through passages 11, the amount regulated by check damper 12. Steam may be admitted at 13 and 13*a*, to regulate temperature of regenerator or water tubes may be inclosed in the furnace walls to take up some of the heat. This regenerator may also be placed alongside of or below the furnace proper. Straight, smooth passages are made in the regenerator which take 2000 to 4000 lb. of gas per square foot of flue area per hour as compared with 500 lb. average in ordinary practice.

The advantages claimed for this combination are a considerable economy in fuel, a low stack temperature, and efficient combustion with long controllable flame. An advantage is claimed in having the regenerator inclosed as a unit with the furnace and in using blowers which give, on account of the high velocity, a sort of eddy or mixed flow to the gases similar to smoke coming out of a stack, whereby a better heat transfer is made. (1,170,397 Feb. 1, 1916.)

Valve Mechanism for Regenerative Furnaces.—A valve mechanism for shutting off the gas supply and stack draft during the reversing operation is patented by LOUIS N. McDONALD of Youngstown, Ohio. During

the reversing of the gases in the regenerative firing system some gas escapes into the chambers which escapes unconsumed to the stack when the valve is completely reversed. In order to prevent losses of this kind it is proposed to connect two sliding valves in the flues, one to shut off the flow of gas and the other the stack draft during the reversing operation. These are suitably connected to the reversing valve and are operated with this valve. With both the gas inlet flue and the stack flue closed, the gas remaining in the checker work will flow into the furnace during the reversing of the valve. Another advantage claimed is that an increased pressure will accumulate behind the gas flow valve, which will fill the checker chamber quickly when the valve is opened. (1,170,301 Feb. 1, 1916.)

Method of Producing Aluminothermic Mixtures.—In making aluminothermic mixtures in the thermit process it has been customary to add 15 to 20 per cent of constituents additional to the aluminium and oxide in order to temper the reaction and to alter the composition of the resulting metal. In order to make it possible to add more than 20 per cent of additional constituents without lowering the temperature of the reaction too much, and thus reduce the cost of operation, a method is patented by JOHN H. DEPPLE of Jersey City, N. J. (assigned to Goldschmidt Thermit Co.). In this method the additional constituents are placed in a separate container (which will melt when heated to welding temperature) and preheated by the waste gases from the torch used in heating up the sections to be welded. This container when preheated to a red heat is then placed in the aluminothermic mixture in the reaction crucible and melts together with that mixture in the mold in which the welding operation is carried on. (1,168,061, Jan. 11, 1916.)

Manganese

Colloidal Manganese Dioxide.—Colloidal manganese dioxide used as a depolarizer for miniature batteries used in pocket flashlights is patented by CARLETON ELLIS of Montclair, N. J. The process of making this material is as follows: Five parts of glucose are dissolved in twenty parts of water and cooled in ice. Four parts of a 10 per cent solution of caustic soda is added and then 100 parts of a 5 per cent solution of potassium permanganate is added little by little while cooling the mixture and stirring. The mass stiffens after this addition, in a few minutes, to a jelly and on standing this begins to contract and break up into blocks with separation of liquid. This is facilitated by heating. When forming the colloidal manganese around particles of mineral or artificial manganese dioxide, the above operation is carried out in the presence of this material. The depolarizer has the property of compacting to a firm mass which can be handled without breaking. (1,169,943 Feb. 1, 1916.)

Phenol

Retort for High Pressures and Temperatures.—A retort for producing synthetic chemicals "such as phenol, alpha naphthol, toluene, creosote, pyrocatechin, and other carbon compounds of similar nature, alkalis and hydrochloric acid, etc.," where high temperatures and pressures are desired is patented by JOHN R. WATSON of Baltimore, Md. This retort consists of a high-pressure metal tube with contracted ends, having on its outside electric heating resistances insulated from the body of the retort. Through one end of the retort is placed a thermocouple for automatically controlling the temperature through suitable electrical connections with the heating resistances. On the other end, which is the feed and discharge end, is

a special cap which screws on and which has within it a stem with cone-shaped end which fits into the end of the retort. When the temperature rises to a certain point this stem (which is made of a metal with higher coefficient of expansion and lower melting point than the retort), expands and helps to seal the retort. Should the temperature and pressure go too high, this stem would become soft and allow of an escape into the outer portion of the cap, giving warning and preventing an explosion. (1,169,893 Feb. 1, 1916.)

Electric Furnaces

Electric Furnace for Gas Reactions.—An electric furnace for carrying out gas reactions as patented by ALOIS HELFENSTEIN of Vienna, Austria-Hungary, is shown in Fig. 2. This furnace permits of the intimate association of solid, liquid and gaseous material and catalyzers may thus be used and secondary products also obtained. Gases which it is desired shall react are introduced through pipe 1, through electrode 3, entering a molten bath 7 which is contained in the conducting bottom 6, forming the other electrode. Above this bath is a granular resistance or reacting material with which the gases commingle and then pass into chamber 8, where condensing agents are introduced through nozzles 9. They then pass through flues 10 into connecting chamber 11.

Examples of reactions which may be carried out are given as follows: 1. Acetylene and nitrogen to hydrocyanic acid. Slag bath of clayey earth with floating granular charge of animal coal or charcoal as contact material. 2. Production of carbon tetrachloride by introduction of chlorine into mixture of charcoal and sulphur vapor. Sulphur chloride is first formed, then acted upon by the carbon to form sulphur and carbon tetrachloride. The sulphur may be either absorbed by a silicate slag bath or recovered in the vaporous state. 3. Combining of silicon and nitrogen to form silicon nitride. A quartz bath, over which is a layer of carbon for reducing silica to silicon is used. Nitrogen passed in through electrode. (1,169,817 Feb. 1, 1916.)

Carbon Electrode Production.—A process of making carbon electrodes in which the gases formed are burned and used to heat the furnace is patented by FRANZ NAGELSCHMITZ of Munich, Germany (assigned to Georg Mendheim of Munich, Germany). In this process the coal or coke and tarry binder for making the electrodes are heated in a furnace with a longitudinally extending channel above it for conducting away the gases. The gases pass out of the furnace through a flue into another flue which is also connected to the heating chambers of the furnace surrounding the working chamber. The gases pass from this latter

flue back into the heating passages of the furnace where they are mixed with hot air and burned. The furnace produces the heating gas necessary for its operation. The electrodes are prevented from oxidizing by the use of a packing medium of petrol-coke. (1,170,313 Feb. 1, 1916.)

Metallurgical Furnaces

Calcining, Desulphurizing and Agglomerating Ores.—In two patents granted to FRANZ MEYER of Uerdingen, Germany, and by him assigned to Dwight & Lloyd Metallurgical Co., of New York City, the inventor discloses the structure of a furnace for roasting and sintering ores in a continuous operation. The principle of the furnace is similar to that used in the Dwight-Lloyd straight-line sintering machine, viz., forming a layer of ore on a grate, igniting its surface and inducing a down-draft through the mass. In the present instance the furnace consists of an annular grate rotatable about a central mast, the latter being hollow and communicating with the several grate compartments by radial conduits through which the gases of combustion are drawn off. The individual compartments beneath the grate surface are formed by annular plates dipping into a water seal and by cross-partition plates similarly dipping into a water seal. In operation, the charge is fed continuously onto the moving grate from a hopper. At a certain point the charge is ignited when passing under a source of heat. Combustion is sustained by drawing air downward through the charge as the grate revolves. The quantity of air thus drawn is regulated by spring valves in the conduits running from the grate compartments to the central mast, the spring valves, in turn, being actuated by traveling over an annular cam-track. The elevations in the cam-track can be so placed and of such magnitude as to regulate the draft, by allowing the valves to be open wide or practically closed. At the charging section of the grate the cams are so high that the valves are practically closed, and similarly at the point of discharge. The latter operation is effected by a plow scraping the sinter from the grates. (1,162,634 and 1,166,142, Nov. 30 and Dec. 28, 1915.)

A desulphurizing furnace patented by LEWIS B. SKINNER of Denver, Col., is illustrated in Fig. 3. The object of the construction is to secure an improved draft system, whereby the gases will be removed from

FIG. 2—ELECTRIC GAS REACTION FURNACE

FIG. 3—ROASTING FURNACE

the furnace with as much heat as possible, thus making them more useful for subsequent purposes, as for the manufacture of sulphuric acid. Another object is to construct a furnace that will avoid the generation of excess heat in the middle hearths, thereby injuring the structure. The furnace is of the superposed hearth type, with a central revolving shaft carrying the rabble arms which sweep over the ore on the hearths and cause its movement from hearth to hearth downward through the furnace. As shown in the figure, the three lower hearths are hollow, or of the muffle type. In order to prevent overheating in the middle hearths, special arrangements are made to vary the draft through the furnace. Thus two outlets for gas are shown at 10 and 11, the former at the topmost hearth and the latter opposite a middle hearth. Intakes for air are provided at 13 and 14, the former at a middle hearth and the latter at the bottom. The amount of air admitted and gas leaving the furnace can be regulated by dampers in the outlets and intakes. The result of this arrangement is that there is a uniform temperature throughout the various hearths of the roaster, and the hot gas in the middle zone is removed with all its heat. In a second patent granted to the same inventor means of radiating heat through the furnace walls are provided in the form of steel or iron plates inserted into recesses in the wall of the furnace. Instead of plates, jackets adapted to air or water cooling may be inserted. (1,164,131-2, Dec. 14, 1915.)

Cerium and Alloys

Cerium Used in Alkaline Storage Battery.—A patent has been issued to THOMAS A. EDISON of West Orange, N. J. (assigned to Edison Storage Battery Co.), for an alkaline storage battery in which the positive element is made up of alternate layers of nickel flake and a cerium compound. The material is prepared as follows: A solution of a soluble salt of cerium such as the sulphate is treated with caustic soda and the precipitate is washed and dried and ignited to a white heat in an atmosphere of hydrogen and then cooled down in hydrogen. The product is finely divided and probably consists of an oxide or mixtures of oxides of cerium. For the negative elements of the battery finely divided iron or iron oxides are preferably used. An electrolyte of potassium or sodium hydroxide is used, having added to it a small percentage of lithium hydroxide. (1,167,485, Jan. 11, 1916.)

Gold Alloys.—Alloys intended to be used as substitutes for certain platinum and palladium alloys are patented by KARL G. P. RICHTER of Pforzheim, Germany (assigned to Dr. Richter & Co. of Pforzheim). The alloys are made by substituting a metal of the iron-nickel group, particularly nickel for metals of the palladium group. In this way alloys are obtained which are not much different in cost from the ordinary gold alloys, while the brittleness produced by the nickel is removed by the combination of the nickel with the noble metal. The alloy is malleable and may be used in jewelry manufacture. Instead of pure gold, copper-gold alloys may be used as the starting material. (1,165,448, Dec. 28, 1916.)

Ductile Alloys of High Melting Point.—Alloys for use in electric lamps, firearms or as tools and instruments for various purposes are patented by HANS KAISER of Augsburg, Germany (assigned to Wolfram-Lampen Aktien Gesellschaft of Augsburg, Germany). These alloys are produced by selecting a metal such as tungsten as a base and adding two additional metals before sintering, the first additional metal, such as thorium, consisting of about 1 per cent, and the second

additional metal, such as platinum or a metal of the platinum group, being added in very small proportion, i.e., about 1/20 of 1 per cent. The addition of the third metal increases the toughness and ductility and reduces the sintering temperature. (1,167,827, Jan. 11, 1916.)

Counter-Migration of Pulp and Solution in Cyanidation and Acid Leaching

BY BERNARD MAC DONALD

CYANIDATION

Since "all sliming" has been adopted as the most desirable condition, generally speaking, to which an ore should be reduced in order to obtain the best results in cyanide treatment, the efforts of metallurgists have been directed largely to the improvement of the plant apparatus, and of the methods previously used for the agitation of the slime and for the separation of the solution from the leached-out "barren" solids in the treated pulp.

Fig. 1 indicates the means by which these essential objects are automatically secured, and the counter-

FIG. 1—COUNTER MIGRATION

migration of the solution and solid constituents of the pulp effected in a series of Parral tanks.

The equipment specially instrumental in bringing about these objects consists of a circular diaphragm, water-tight at the sides, open at the top and bottom and supported centrally in the upper portion of the tank. This diaphragm extends vertically down below the pulp level to a certain depth designed to meet conditions, which, for this description, is assumed as 8 ft., and above the pulp level to the height of 2 ft. In this position the diaphragm divides the upper position of the tank into two areas, the annular space between the side of the tank and the diaphragm known as the "agitation circle" and the space inclosed within the diaphragm known as the "separatory area."

The solution and solids in the pulp to be treated may be in any suitable ratio, but for a definite description the usual 2:1 ratio is assumed. In this ratio the pulp contains two parts of solution to one of solids by weight, which gives it a specific gravity of 1.26, or about one and a quarter times the weight of the same volume of water.

In operation the pulp to be treated flows in a continu-

ous stream through a feed pipe which delivers it in the agitation circle two or three feet below the pulp level where it is merged with the pulp in agitation there.

The agitation of the pulp is effected by the mechanical means peculiar to the Parral tank system.

Four transfer pipes, each 6 in. in diameter, are set at quarter points in the tanks, their lower or intake ends reaching within a few inches of the tank's bottom, and their upper or discharge ends emerging about 4 in. above the pulp level. The discharge ends of these pipes are fitted with tees or ells with their discharge openings directed so as to discharge in the same direction around in the agitation circle. Half-inch pipes connecting with the compressed-air main outside the tank are fixed centrally within the transfer-pipes and terminate in a ball-nozzle-valve at a point about 5 in. above their lower ends. Compressed air having a pressure of say 10 per cent higher than the static pressure due to the pulp depth in the tank is introduced through this connection into the transfer pipes which are operated as air lifts. In operation the transfer pipes throw continuous streams of pulp, transferring it from the bottom and delivering it on the top of the tank charge. The spouting force of these streams discharging in the same direction at the surface of the pulp mass in the agitation circle sets up and maintains a rotary flow in the pulp which extends from top to bottom of the tank.

This flow and the continuous withdrawal of the pulp from the bottom of the tank and its redistribution over the surface of the tank charge, gives it the required aeration and keeps its solution and solid constituents in proportionate mixture, a condition which is essential for the effective dissolving out of the metals in the solids.

While the agitation of the pulp is going on in the agitation circle the area within the diaphragm remains absolutely quiet, with the result that the solids settle rapidly out of the contained pulp and sink to the bottom of the tank, there coming within the suction range of the transfer-pipes, they are transferred to the surface where they are carried away in the rotary flow. As the solids settle out of the solution within the diaphragm the clear solution remains in hydrostatic balance with the denser pulp in the agitation circle. This pulp, as above stated, having specific gravity of 1.26, will balance a column of clear solution one and a quarter times its own height. Therefore, the 8-ft. column of pulp outside the diaphragm will raise the clear solution to a height of 10 ft., or 2 ft. above the pulp level in the agitation circle. At the height of 7 ft. 6 in. on the inside of the diaphragm is fixed an annular launder, into which clear solution rising within the diaphragm overflows continuously. From this launder a pipe conducts the clear solution over the top edge of the tank, and delivers it into the agitation circle of the next tank adjoining where it becomes mixed and agitated with the pulp and is again separated from it as above described.

As the solution is thus migrating from tank to tank in each of which it is mixed and agitated with new pulp flowing in the opposite direction, it dissolves out and takes up the metals contained in the solids and thus becomes richer while the solids become poorer as they pass from tank to tank. When the solution is separated from the head tank of the series it is sent to the precipitation room where the values held by it are precipitated and the solution, now barren, is returned to the tail-end tank of the series, where it begins again its migration through the tank series, repeating the same effect above outlined.

The tail end of each series of treatment tanks consists of two tanks used for the settlement of the pulp and decantation of all the solution possible from the pulp before it is discharged to the filter or dump. The

equipment of these tanks is similar to the others, but the pulp is received alternately in them, which allows of intermittent settlement, decantation and agitation by which all the solution consistent with flowage is removed from the pulp.

The volume of compressed air consumed in operating the transfer pipes is very small, owing to the fact that the pulp is transferred through them from the bottom to the top of the tank charge under practically hydrostatic balance—a lift of only 4 in. above the pulp level being required. The volume of the streams of pulp transferred may be regulated to any quantity desirable by the valves on the compressed air pipes.

ACID LEACHING

The method of agitation and the counter-migration of the pulp and solution above described is applicable and especially advantageous in the leaching of copper ores by sulphuric acid solution. In this treatment of copper ores the methods are analogous, almost identical with cyanidation, except that the solution being acid requires acid proof apparatus for the agitation of the pulp and the manipulation of the solution.

For copper leaching the Parral tanks and all their equipment are made of wood and are unaffected by the acid solutions. The almost complete separation of the metal-laden solution from the leached-out pulp that is possible to make in Parral tanks by the method described, which obviates the necessity of filtering—the most difficult part of acid leaching—makes this method of treatment worthy of the serious consideration of those engaged in the hydrometallurgy of copper ores.

Los Angeles, Cal.

Paper Thread and Cloth

A Substitute for Cotton

The war has shut off a great many raw materials from Germany which are needed in her industries. This has forced her to invent new materials which suit old purposes but are made from raw materials which can be procured at home. In many ways the ingenuity of the German chemists has manifested itself. One industry which has received attention for this reason is that of paper thread and cloth; it has become important because the cotton supply was practically shut off. A summary of this industry is given in the *Zeitschrift des Vereins Deutscher Ingenieure* Jan. 8, 1916, by W. HEINKE. These products have been made in Germany for a number of years without a very general knowledge nor broad application. The paper and textile industries are responsible for their production, and the process is based on Japanese processes in use for 100 years.

The raw materials used are wood cellulose, sawdust, old paper, rags, rope, or waste from the cotton, jute, flax and hemp spinning industries. These are made into paper, and this paper is then cut into strips by machinery and twisted into thread or used untwisted as a substitute for jute thread and cotton thread in linings, carpets, sacks, and other material. The Japanese have for a long time used paper cloth for various purposes, but it remained for Germany to develop machines for cutting and spinning, and create a good-sized industry. At present the cellulose used is mostly from pine and cypress.

A modern strip cutting machine for cutting the paper into strips can cut (according to the makers) 3000 kilograms of paper stock in 10 hr. in strips up to 10 mm. width. Only one workman is needed for this machine. After cutting, the strips are moistened and spun into thread on the spinning machine, which may be of several different types.

FIG. 1—TWISTING OF DRY PAPER STRIP

FIG. 2—TWISTING OF MOISTENED PAPER STRIP

It is necessary to moisten the strips before spinning, otherwise they will crumple and tear and will not stand the spinning. On the other hand they must not be made too moist, otherwise their strength will be impaired. In Fig. 1 is shown a dry paper strip in the process of turning, which is probably ready to tear. Fig. 2 shows a moistened paper strip spun into a thread. The spinning must not be carried too far or the paper will naturally tear.

The cutting machines are usually of the revolving cylinder type, the paper stock passing between two cylinders. On the upper cylinder the knives are placed, spaced according to the width desired and fitting into grooves on the lower cylinder, the knives being held fast to one edge of the groove. After cutting the paper, it is either wound on spools or is moistened and conducted directly to the spinning machine. For moistening it is run over a cylinder which is moistened by another cylinder touching it and passing through a tank of water below its axis.

The spinning machines have reached quite a high degree of perfection and are described in some detail with illustrations in the original article. They all accomplish the same purpose, but differ only in mechanical details. An improved machine, known as the plate-spinning machine and manufactured by Aktien Gesellschaft Karl Hamel in Schönaue, is shown in Fig. 3, and will give some idea as to the extent that this industry is being developed in Germany.

The microscope has come into use in observing the tensions at different stages of the spinning. Practical colors can be produced on the woven fabric by chemical means, and the paper cloth has found considerable use in covering threads of jute, flax, and cotton, giving them a smooth appearance, and covering up loosely spun threads which would make them rough. Unraveling is also prevented, and in the packing of goods with jute this is of considerable value. Metal wire is also covered

with this paper material. The paper thread is also woven with textile thread, and the product not only possesses the outward appearance of textile goods, but is also more firm.

Quite a number of machines have been patented in Germany during the last year for the covering of thread and wire by spinning paper thread over it. Machines have also been devised for covering paper thread with textile thread, and the various uses to which this paper seems to be applicable are evidently unlimited.

By different means it has been tried to make the paper thread waterproof for application in special fabrics. As a result of the war, which produced a shortage of jute and cotton thread, this question is important and a means will probably be found for waterproofing paper threads. For binding twine as well as for sacks the paper thread finds considerable use. The paper thread gives them a certain firmness along with flexibility. The paper thread is not spun to obtain a great firmness as in common textile spinning, but chiefly to give it a round form with the flexibility. Paper threads tested by the author gave strengths on stretching five to six times that of the original paper strip.

As a rule the same twisting frame can be used for weaving paper cloth as for weaving textile cloth. Cloth going by the trade name of "textilose" is a combination of paper and cotton or jute, the cotton or jute usually glued on both sides of the paper. "Textilin" is made by folding and pressing paper strips by a special machine instead of spinning them.

Factories and private experimenters have been quietly working for ten years on the problem, and it is expected that the industry will reach large proportions. From this side of the Atlantic it would seem that the boom of this new industry has been caused by the present shortage of cotton in Germany. Yet necessity is the mother of invention, and many times a new industry has only begun to flourish after the peculiar economic conditions which brought it into existence have ceased to exist.

Development of a Modern Ball-Mill

The use of ball-mills for grinding ore is probably adapted from the cement industry, where such mills were most successfully used for fine grinding of the clinker. Perhaps an earlier use of similar apparatus can be found in the familiar "rattler" of the foundry, which is used to clean castings of various sizes by allowing them to tumble over each other in a revolving cylinder.

The simplicity and efficiency of this type of grinding apparatus has led to its wide adoption in ore treatment, where it has found favor over other forms of grinding apparatus. In its earlier use, in the form commonly known as the tube-mill, flint pebbles were used as the grinding medium and the lining was made of siliceous blocks. Other forms of lining have been developed, such as the El Oro, in which the pebbles become wedged between iron bars and thus become the lining. The tube-mill is essentially a long cylinder, having a length of from 4 to 4½ times the diameter. Considerable discussion has centered on the requisite length of such mills, many authorities contending that practically all the efficiency of the tube was found in the first few feet from the feed end, and that nothing of consequence in the way of further grinding was accomplished near the discharge end. This has led to the shortening of the tube, thereby reducing the first cost and lessening the power requirement. In at least one case that has come to notice this contention regarding the efficient grinding zone in the long tube-mill seems to have been

FIG. 3—PLATE SPINNING MACHINE

established. The tube was $4\frac{1}{2}$ ft. by 18 ft. After being in service for a long time it became leaky, so that pulp discharged at various points along its length. The operator collected samples of the pulp thus discharged, and on making screen analyses of the discharge at various points along the length of the tube he found that practically no efficient grinding was done in the last 14 ft.

Probably the first ball-mills successfully used were made by Krupp of Germany, and were applied in dry crushing. These mills had a screen at the periphery outside of the liners, the latter being so arranged that when the ore was partly ground it would emerge through openings which were somewhat larger than the screen openings that determined the size of final product. That portion of the material that did not pass through the outside screen re-entered the grinding portion of the mill.

The next development of any consequence was Hardinge's conical mill, which, instead of having a cylindrical grinding chamber, is composed of two cones with their bases attached to a short cylinder. One of the cones, at the feed end, is shorter than the one through which the pulp discharges. A high efficiency is claimed for this mill, due to the selective action of the pebbles or balls used for grinding, whereby the larger balls or pebbles remain in the center of the mill and grade to smaller sizes toward the discharge. As the ore particles tend to arrange themselves in similar manner, the larger balls or pebbles work on the larger pieces of ore with intermediate gradations down to the smallest pebbles and smallest particles of ore. Thus it is sought to apply energy as needed in accordance with the size of ore particles.

In this type of mill, however, as with all tube-mills which discharge their products at about the same level with the feed, we have a selective action giving a classified product in which a fine particle of heavy mineral is discharged with a larger piece of light gangue. Since the minerals in an ore are frequently softer than the accompanying gangue, this action may have the effect of grinding mineral finer than is necessary, especially where crushing and grinding are being done for subsequent ore-dressing and not for sliming as in cyanidation.

An earlier type of ball-mill, which in some respects embodied the ideas of the latest types, was known as the Ferraris. It was on the market for a time, but owing to a defect in design which will be pointed out later it did not come into wide use. This mill is illustrated in Fig. 1. It consisted of a revolvable drum divided into two compartments, *A* and *B*, by an annular perforated partition *a*. The larger or crushing compartment *A* was lined with ribbed steel plates and contained forged steel balls varying in size from 3 to 6 in. The smaller or screening compartment *B* was divided into a series of pockets by means of radial partitions extending from a cone *b* that projected back into

FIG. 1—FERRARIS BALL-MILL

FIG. 2—MARCY BALL-MILL

the crushing compartment. The periphery of the screening compartment was open and surrounded by a screen of the desired mesh. When the ore was ground fine enough to pass the perforations of the annular partition it flowed into the screening compartment and out through the peripheral screen into a housing surrounding the lower part of the compartment. That portion which was not ground fine enough to pass the screen was elevated by the radial partitions in compartment *B* and slid back on the surface of the cone into the crushing compartment *B*.

In the light of later experience the failure of this mill to perform as expected was due to the fact that the oversize was returned at a point where there was little or no chance for further grinding. Had the entire pulp, after passing the annular partition, been screened outside the mill and the oversize returned at the feed end, there would have been effective regrinding; but when it was returned to a point just inside the annular partition there was no opportunity for further grinding, as the oversize immediately short-circuited through the partition and accumulated until the mill was choked. Nevertheless the Ferraris mill may be regarded as the forerunner of the modern short ball-mill, embodying as it did the perforated partition with low discharge and

FIG. 3—ANNULAR GRATING AND LINING MARCY BALL-MILL

the radial lifters. But for the failure to recognize the necessity of outside screening and return of oversize at the feed end, we might have had the modern short ball-mill years ago.

In the development of the modern short ball-mill we endeavor to provide a crushing machine in compact form that will take feed up to 3 or 4 in. in diameter and reduce it to, say from 10 to 60-mesh, according to requirements, in one operation, the product being screened or classified outside the mill and the oversize returned with original feed. The grinding medium is steel balls and the lining is of such form as to provide a series of steps or corrugations which lift the charge as the mill revolves. This has the effect of causing the ore and balls to cascade, the former being crushed by impact of the latter. Early experience with such mills showed that they were efficient grinders, but when used with trunnion or overflow discharge on practically the same level as the feed they were subject to the criticism previously mentioned, viz., that the heavier mineral remained in the mill longer than was necessary and was consequently ground too fine. It was to obviate this condition and to produce what might be called an unclassified or non-selective product, that brought about the next important development in ball-milling, viz., discharge at a lower level than that of the feed.

One of the recent mills of this type is known as the Marcy, manufactured by the Mine & Smelter Supply Co., Denver, Colo. As shown in Fig. 2 it consists of a cylinder of greater diameter than length, say 8 ft. by 6 ft. The interior is divided into two compartments by an annular grating of manganese steel, which is well illustrated in Fig. 3. This view also shows the nature of the ribbed lining of the grinding compartment, composed of sectors bolted in place. In the discharge compartment, that is between the grating and the discharge end of the tube, there is a series of pockets formed by radial lifters corresponding to the sectors of the grating, much the same as in the Ferraris mill. The grating has linear openings $\frac{1}{8}$ in. wide or less, increasing in width toward the discharge compartment.

The feed end of the mill is fitted with scoop feeders which deliver the ore to the grinding compartment. When the ore is crushed fine enough to pass the grating it flows into the discharge compartment where it is lifted by the radial bars and discharged through the trunnion. In this respect the Marcy mill differs radically from the Ferraris, for the entire pulp is removed from the mill for screening or classification, and the oversize is returned with original feed. Due to the ease with which ground particles pass through the grating, and the rapidity with which they are removed by the lifters, the level of discharge from the grinding compartment is much lower than that of the feed, and as a consequence mineral and quartz particles are removed from the grinding zone with equal facility, and almost as soon as they are ground. This obviates the unnecessarily fine grinding which occurs in a mill with trunnion discharge on about the same level as the feed, wherein the particles have to rise to a high level in order to flow out.

Mills of this type are now being constructed that will take feed as coarse as 4 in. in diameter and deliver a product of 40 or 50 mesh. This makes it possible to eliminate some of the machines heretofore considered necessary in stage crushing in order to reduce ore fine enough for concentration. The best efficiency has been obtained with about 40 per cent moisture in the pulp. The 8 ft. diameter by 6 ft. long mill has a capacity of 1000 tons per twenty-four hours, grinding to 10-mesh; 750 tons to 20-mesh; 350 to 400 tons to 60-mesh. These capacities have been shown on Arizona copper ores. The

power requirement is from 200 to 225 hp., and the ball load from 9 to 10 tons. The balls range in size from 5 in. diameter, weighing 20 lb., to $2\frac{1}{2}$ in. in diameter. The Inspiration Consolidated Copper Co. has installed forty of these mills at Miami, Ariz., each having a capacity of from 350 to 400 tons per day, taking crusher feed as coarse as $2\frac{1}{2}$ to 3 in. and delivering a product that will pass a 48-mesh screen. These mills are in closed circuit with classifiers which deliver the oversize back to the feed end. The cost of crushing, including power, oil, maintenance, etc., is stated to be less than 15 cents per ton, and it is hoped eventually to reduce this to 10 cents per ton. Metal consumption of balls on copper ore amounts to about 0.6 to 1 lb. per ton, while the lining consumption is about one-tenth of this amount.

The simplicity of the modern ball-mill, compared with the Huntington, Chilean and other grinding machines, seems to warrant the belief that it is destined to replace many other forms of mills. It is practically fool-proof and the horsepower required is less than for the machines mentioned, considering mesh-tons crushed. The ball-mill is rapidly coming into use for concentration, cyanidation, flotation and amalgamation, in fact, for all processes in which wet crushing and grinding are used, excepting, of course, where coarse concentration by jigging is desirable.

The Present Situation in Graphite Crucibles

The crucible manufacturers have been put to sore straits for the past eighteen months in the securing of their raw materials.

First came the embargo on Ceylon plumbago. This was lifted after a few months, but the market was left in a depleted condition. The natural result was a tremendous advance in price.

Next came the exhaustion of the foreign clay which is used in crucible making as a binder. As far back as crucible history in this country goes the clay used has come from the little Principality of Klingenberg in the Black Forest of Southern Germany, where, so the story goes, the entire government expenses are paid out of the export duties collected from the clays shipped out. This Klingenberg clay has for years past been the only clay which the crucible makers seemed to think could be satisfactorily used. No shipments of this clay have been made since the beginning of 1915.

Some makers have husbanded the enormous supplies of the foreign clay which they had on hand when hostilities started. This husbanding the stock of the now almost priceless raw material has been done by partially substituting clays from various parts of the United States and mixing them with the Klingenberg clay.

The tests and trials made by the crucible makers during the past twelve months have been almost endless. When it is taken into consideration that it takes from six to ten weeks to prepare a graphite crucible for service in the foundry, some idea can be formed of what the crucible maker has to contend with. Added to this delay and before he can even start on these goods that will not be marketable for two months to come, the chemical laboratory tests and trials must be made. These have run into the thousands. Then must come the practical tests in a small way in the foundry; for the crucible maker would stare bankruptcy in the face if he continued making up hundreds of thousands of dollars worth of goods out of Ceylon plumbago, costing from $17\frac{1}{2}$ to 25 cents per pound, only to find at the end of two or three months that they might not be of service to the user.

The bright side, however, to all that is that in many cases the crucibles made with American clays have stood a surprisingly long time in the fires. In one case there is a report on a No. 300, which ran forty heats on manganese bronze, and dozens of cases as high as thirty-eight and forty heats on No. 100's melting car box metal. The chief trouble now seems to be some lack in uniformity of the products secured. Crucibles made by the same potter out of similar materials, at the same time, and burnt in the same kiln, when run by one melter on the same grade of metals are liable to behave so differently from each other that it is a shock to both user and maker.

All this will in time be rectified. As soon as the manufacturers have become more familiar with the mixing and blending of our native clays, they will no doubt be able to produce in time a crucible as satisfactory as or superior to those manufactured heretofore from foreign materials. The user, however, must use more care in handling the American clay crucibles.

It is imperative that these crucibles are thoroughly dry and warm before going into the fire, and that they are heated up *very slowly* on the initial heat.

Some users make a little fire with charcoal inside the crucible, and others put hot ashes in, before placing the pot in the fire, so that the crucible is hot when it goes into the fire for the first heat. There are certain advantages in heating the crucible first from the inside rather than the outside.

Great care must be taken in the matter of wedging, as American clays have not the same tensile strength when hot, as foreign clay.

The advance in prices of crucibles is due to the unusually high price of Ceylon plumbago just at present, but as soon as the war insurances are a thing of the past plumbago will be at a normal figure once more, and crucibles will again be marketed at as low prices or lower ones than they have been for many years past.

A New Electrolytic Oxygen and Hydrogen Installation in a Shipbuilding Plant

At the present time most large users of oxygen for commercial purposes are purchasing it from the manufacturers, having it shipped to them in cylinders containing 200 cubic feet at 1800 lb. pressure. As this entails freight expenses and handling at point of consumption, various large users of oxygen for welding and cutting purposes have installed or are installing their own generating apparatus at their plants.

A new electrolytic oxygen and hydrogen plant just finished and put into operation by the National Ox-Hydric Co. of Chicago at the works of the Fore River Shipbuilding Corporation, Quincy, Mass., is complete in every detail, self-contained, and is run entirely automatically, requiring only the attention of one man to a shift, the plant being run continuously by three men in three eight-hour shifts.

The plant consists of a 75-horsepower Bessemer crude-oil engine, belt-connected to a 45-kilowatt direct-current generator; one of the National Ox-Hydric Co.'s electrolyzers, as shown in the adjoining illustration, guarantees to produce 3500 cubic feet of oxygen per 24 hours and twice that amount of hydrogen; suitable gasometers, compressors, motors and switchboards for control.

The oxygen and hydrogen, after being produced from the electrolyzer, passes into steel gasometers of 2000 cubic feet capacity each. From there they pass through a suction line into suitable compressors, which boost the pressure in the pipe lines between the gasometers and point of consumption to the amount

required at the blowpipes. Between compressors and blowpipes or operating stations, are suitable concussion tanks to take the pulsation of the compressors off the pipe lines.

The plant at the works of the Fore River Shipbuilding Corporation is also equipped with high-pressure compressors for the purpose of compressing oxygen and hydrogen into cylinders where it is not advantageous to run pipe lines, such as on board ships and other extreme points of the company's shipbuilding yards. The erection of this plant was begun on December 15, 1915, and entirely completed by February 1, 1916. It is installed in a building of pressed sheet steel 24 x 40 feet.

The National electrolyzer is of the improved filter-press type. The present perfected machine is the result of years of study and experiment on the part of expert gas engineers, whose experience and knowledge are based upon extended and exhaustive research and whose work has made it possible for the company to produce a simple and inexpensive method for the production of oxygen and hydrogen gases at a low initial cost.

Fundamentally, the National filter-press type of electrolyzer consists mainly of a number of decomposition chambers connected in series. These chambers are formed by clamping together a series of cast-iron electrodes so recessed and grooved that each plate forms, with its neighbor, a chamber which holds the electrolyte, and in which the generation of the gases takes place.

The electrodes are carefully insulated one from the other by means of patented rubber-bound asbestos diaphragms. The electrodes and diaphragms are arranged alternately and are supported by the insulated frame of the filter press. The required number of electrodes and diaphragms with the corresponding end plates are then pressed tightly together by means of a heavy screw standard, thus making the whole equipment form a hermetically sealed tank of the filter-press type, the diaphragms serving both as an insulation and gasket, and serve to form the sides of the cells, preventing any mixture of the two gases generated. The fact that the electrodes are thus separated by the diaphragms causes one side of the plate to act as the anode of the chamber and the other side as the cathode of the adjacent chamber.

The electrodes are composed of a special alloy, and are heavily coated with nickel, which makes them neutral to oxygen and alkali (from the potash) and prevents the formation of deposits or the oxidation of the electrodes themselves.

The number of chambers required is, of course, dependent upon the production of gases required, as well as the voltage of the electric current. The elec-

FILTER PRESS ELECTROLYZER FOR THE PRODUCTION OF OXYGEN AND HYDROGEN

trolyzers of the National Ox-Hydric Co. are designed for any standard direct current circuit, or, with the use of a motor-generator set, for any of the standard alternating current circuits, thus doing away with the inefficient low voltage, high amperage necessary with the individual-cell type installation. Furthermore, these electrolyzers occupy about one-fifth the floor space, and in many instances less than one-fifth of the floor space, required by the individual cell type.

By the design of electrode the anode and cathode are brought close together, so as to reduce to a minimum the electric resistance, while at the same time the hydrogen gas is effectually kept separate from the oxygen gas without preventing the proper passage of the electrolytic solution between the anode and the cathode.

The electrodes themselves are made with corrugated surfaces, increasing the active electrode surface and forming a large number of very small vertical channels through which the gases rise freely to the upper part of the plates. At the top of each electrode and hermetically sealed together are substantial chambers in which the gases are separated from the electrolyte. From these chambers the gases pass off in a dry state into ducts extending through each plate, these ducts forming continuous conduits, owing to the manner in which the plates are assembled. The gases pass through these conduits into their respective receivers or storage tanks. One of the main features of the design is the way in which the conduits are kept free from electrolyte; this is accomplished by one of the most practical devices known to the gas industry, which device is cast integral with each plate, thereby eliminating any possibility of a short circuit even should the conduits become filled with the solution.

The electrolyte is a 21 per cent solution of pure caustic potash in distilled water. After the electrolyzers are once filled with this solution, distilled water is added from time to time to take the place of the water decomposed; the potash lasts many months. The distilled water is fed to the electrolyzer by an automatic device which maintains a constant level of the electrolyte throughout the machine.

Under normal load conditions, the voltage required per cell is two volts or less. Therefore, to operate on a 110-volt circuit an electrolyzer containing 55 cells is necessary; and on the same basis, 110 cells are necessary for a 220-volt circuit.

The positive pole of the direct-current dynamo is connected with the first electrode in the series, and the negative pole is connected to the last electrode of the series.

The apparatus is provided with one collector for hydrogen and one for oxygen, whereas, the individual-cell type system must have a separate draw-off, or collector, for each cell in use, which necessitates more labor and a considerable increase in upkeep.

Insulation difficulties have been eliminated which prohibit short-circuits and groundings and make the cost of maintenance very small, the labor operating cost being practically negligible.

Assuming continuous operation and normal load conditions as specified by the company, the electrolyzers yield 4 cu. ft. of oxygen and 8 cu. ft. of hydrogen at atmospheric pressure per kilowatt hour of power consumed when the plant is operated at a temperature of 68 degrees F.

The gases produced are of very high purity. The oxygen is of 99.5 per cent purity. The electrolyzer will stand an overload of 50 per cent without any ill effects. This feature of being able to considerably

overload the plant and generating a proportionally greater amount of gas is of great advantage.

The operator of one of these electrolyzers should in all cases make a chemical analysis at regular periods of the oxygen and hydrogen gases produced, testing their purity. Other than that his only duty is to maintain a proper water column level of the electrolytic solution.

The water of which the electrolyte is formed has to be distilled in the large commercial plants by means of a properly installed still, but in the smaller individual plants the purchase of distilled water in quantities sufficient to successfully operate the plant is advocated.

The electrodes are practically indestructible. The asbestos diaphragms are very durable, and being neutral to the elements with which they come in contact, have a life fully equal to that of the electrodes. All other parts of the equipment are practically not subject to any wear and tear.

Industrial Notes

The Benzol Products Company, Marcus Hook, Pa., will erect a research laboratory and make other additions to its plant representing an expenditure of \$45,000.

The American Coal Products Company, it is officially announced, has decided to unite its name with that of the Barrett Manufacturing Company and the new name will be the Barrett Company. The new company will have the same amount of stock as the American Coal Products Co., which concern was the parent organization of the Barrett Manufacturing Co. and owned its stock.

The International Acheson Graphite Company of Niagara Falls, N. Y., has changed its name, and hereafter will be known as Acheson Graphite Company. It will be noted that the word "International" has been dropped and that the company name now begins with the name of the noted inventor of the process for making graphite artificially in the electric furnace. The change was brought about through the conception that the word "International" had no significance in the company's business and only served to conceal the identity of the company when indexes and other references were examined for the name and address.

The Stupakoff Laboratories, Pittsburgh, Pa., are erecting new laboratories on Hamilton Avenue, and during the erection they are temporarily located at 6364 Frankstown Avenue.

New Lining for Combustion Boats.—The Scientific Materials Company, Pittsburgh, Pa., has placed on the market a new material known as sinderite for lining combustion boats for direct combustion of carbon in steel analysis. The material was developed by the company's research department and is stated to be free from carbon and not to absorb CO_2 from the atmosphere, while possessing other valuable properties which make it a protection to platinum and the combustion tubes.

The Bausch and Lomb Optical Co. has issued a catalog describing its optical instruments for inspection and testing of materials. This includes microscopes and photomicrographic outfits for the examination of ores, metals, rocks, concrete, wood, leather, fabrics, paints, varnishes, oils, dyes, inks, drugs, chemicals, and foodstuffs.

The Chain Belt Company, Milwaukee, Wis., has issued a supplement to their general catalog No. 56. The supplement contains revisions of the general catalog both pertaining to prices and dimensions.

Annealing Cast Bronze.—A study has been completed by the Bureau of Standards, of the annealing of bronze; zinc bronze (copper 88, tin 10, zinc 2) as a type and the results published in Technologic Paper No. 80 which may be obtained without charge from the Bureau of Standards, Washington, D. C. The title of the publication is "Microstructural Changes Accompanying the Annealing of Cast Bronze."

Safety-First Exposition.—A safety-first exposition by government bureaus was held at the New National Museum in Washington, Feb. 21 to 26. Twenty-six bureaus participated in the exposition and apparatus in use by the federal government was demonstrated by experts.

Experiments in Use of Niter Cake.—In the search for a substitute for sulphuric acid, several mills in Yorkshire, England, have carried out experiments in use of niter cake, according to Commerce Reports. The experiments were made in connection with the extraction of grease from suds, for the refining of grease, and other purposes. The chief difficulties are those of handling, drawing of the acid liquid in storage and handling, and difficulty in transportation. The best method is said to be to dissolve the cake in hot water by the aid of steam and to use this solution hot.

Chemical Engineering at University of Michigan.—A special bulletin has been issued by the University of Michigan describing the chemical engineering course and graduate fellowships in gas engineering metallurgy, paint and varnish manufacture, and pulp and paper manufacture. The chemical engineering department, since its foundation in 1898, has been an integral part of the College of Engineering.

Pittsburgh Section American Electrochemical Society.—The regular meeting of this section was held on Jan. 14, Prof. S. L. Goodale spoke on "Some Observations on the Heat Treatment of Steel," illustrated by a projecting microscope using actual etched samples. C. G. Schluederberg was elected chairman and H. C. Ray, secretary-treasurer for the coming year.

The Montana Section of the American Institute of Mining Engineers held its annual meeting and banquet on Feb. 14, at the Silver Bow Club, Butte, Mont. The following officers were elected: Chairman, J. L. Bruce; vice-chairman, W. C. Siderfin; secretary-treasurer, M. H. Gidel; executive committee: N. W. Braly and W. T. Burns. The speakers were Prof. D. C. Bard, who talked on oil prospecting, and Frederick Laist, who talked on zinc metallurgy as practised at Anaconda.

Cornell's Chemical Department Burned.—Morse Hall, seat of the chemistry department of Cornell University at Ithaca, N. Y., was destroyed by fire on Feb. 13. Much valuable apparatus and chemicals were consumed and the loss is estimated at \$300,000. The main building was erected in 1890 and it was twice enlarged, Andrew Carnegie giving \$60,000 for a recent addition. Several hundred students saved books from the library on the first floor, and the records of the department. Insurance to the value of \$200,000 was carried.

Rope-Operated Controllers for Small Cranes and Hoists.—A new reversible drum-type controller designed for overhead mounting, with rope operation is being introduced by the Cutler-Hammer Mfg. Co., Milwaukee, Wis. These controllers are designed for installation indoors for intermittent speed regulating duty, such as in crane and hoist service. Two types are made, one giving 50 per cent speed reduction under half full load current and the other 90 per cent under light load conditions.

Compound for Removing Scale.—A substitute for sulphuric acid for removing scale from iron, steel, brass, copper, etc., which is finding increasing use at present

on account of the high cost of acid is manufactured by the Research Mfg. Co., Oak Lane Station, Philadelphia, Pa. Special progress is being made in the following trades: rods, flats and tubes to be cold drawn; sheets to be tinned or galvanized, brass and copper shells, some grades of castings and forgings. It is adapted for the removal of scale from any metal whether for pickle finish, cold drawing, tinning, galvanizing or enameling. The compound, which is known as Edis compound, is shipped in dry cakes and can be handled readily. It is dissolved in water and heated to 180 deg. Fahr. for use. The vapor is claimed to be non-irritant and not injurious to health.

Personal

Dr. John A. Brashear, past president of the American Society of Mechanical Engineers, will be the guest of honor at a banquet given by the Engineers' Society of Milwaukee, Wis., on March 21.

Mr. W. T. Burns has been promoted to the position of superintendent of electrolytic refineries for the Anaconda Copper Mining Co. at Great Falls, Mont., and will have charge of both the copper and zinc electrolytic plants. Mr. E. E. Brownson, formerly chief chemist, has been promoted to be assistant superintendent of the electrolytic copper refinery.

Mr. Herman A. Holz, who has been connected with the Scientific Materials Co. of Pittsburgh for the past five years, has opened offices and showroom in the Hudson Terminal Building, 50 Church Street, New York City. Mr. Holz will deal in precision instruments of high quality for industrial, scientific and military purposes, and will make a specialty of metallurgical research and testing apparatus, pyrometers and hydrostatic recording instruments for pressure, vacuum, volume and velocity of air and gas currents in industrial plants.

Mr. Woolsey McA. Johnson is making a professional trip to Kansas and Oklahoma and expects to return in about two months.

Mr. John G. Kirchen, general manager for the Tonopah Extension Mining Co., has been elected president of the Nevada Mine Operators' Association.

Mr. David H. Ladd of Houghton, Mich., formerly metallurgist of the Wallaroo smelter, Australia, has been appointed general manager of the Sandusky Foundry, Sandusky, Ohio.

Messrs. Dorsey A. Lyon and O. C. Ralston of the Salt Lake office of the U. S. Bureau of Mines, are making a field trip through the central West investigating the general subject of flotation. They held a conference with other metallurgists at Lawrence, Kan., with a view to arranging co-operative work on flotation experiments and research.

Mr. Wm. H. Nichols, Jr., has been elected president of the General Chemical Company, succeeding Sanford H. Steele, who retired to become general counsel of the company.

Mr. H. O. Swoboda has been engaged as consulting engineer by the Humphrey Company of Kalamazoo, Mich., to design a line of electric water heaters.

Messrs. Theodore S. Tenney and Arthur K. Ohmes will continue in business as consulting engineers for heating, ventilating and power plant work at 101 Park Ave., New York, under the name of Tenney and Ohmes. Mr. Werner Nygren has withdrawn from the company and will practice independently at the same address.

Dr. Ludwig A. Thiele announces his establishment as an independent consulting chemical engineer with special knowledge of the design and construction of acid and fertilizer plants. His office will be in the Hartman Building, Columbus, Ohio.

The Place Value of Waterpowers

In this issue we publish an interesting letter by "A. C." who asks whether we are not becoming unduly excited over Niagara power, and suggests the possibilities of cheap power from gas and the prospects of developing other waterpowers outside of Niagara. His are sensible questions. There is no doubt that in the directions indicated by him an enormous amount of hard and progressive work remains to be done. Think alone of the existing beehive coke ovens and what could be done with by-product coke ovens. Other waterpowers than Niagara in other parts of the country also have a serious right to be taken into consideration. As a single example, Muscle Shoals on the Tennessee River, if developed, might offer an excellent location for a cyanamid factory—with the Southern fertilizer market at its doors and protected by its inland location against foreign aggression if the factory should be turned over to making nitric acid for explosives in case of war. But this example also brings out clearly one point which is usually overlooked, that is the "place value" of a waterpower. As things are, most of the potential sources of cheap power which remain to be developed, will be linked to certain specific industries by considerations of raw materials supply and market.

Dr. Baekeland some ten years ago said that one chief factor determining whether a chemical process would work successfully, was Mr. Edward Harriman. Mr. Harriman is dead, but Dr. Baekeland's remark is as true to-day as it was ten years ago. That transportation costs play an enormously bigger part in the industrial life of this country than that of any other country, can be shown by a few indisputable comparative figures. As a basis we will use a few figures given by Mr. J. R. Finlay in his admirable paper on "industrial energy as a military weapon," published in our issue of Sept. 1, 1915 (Vol. XIII, p. 547). Mr. W. L. Saunders, in his speech last month before the New York section of the American Electrochemical Society (our issue of March 1, 1916, p. 259), based his convincing argument on a similar line of thought. Mr. Finlay considers as one chief criterion of a nation's industrial activity the consumption of fuel. This is 5 tons per capita for the United States, 4 tons per capita for England and Germany, 1.6 tons per capita for France, 0.25 ton per capita for Russia. These figures are a direct indication of the degree to which a nation has succeeded in multiplying the natural working productiveness of its average citizen by industrial development. Clearly the United States is easily the foremost industrial nation; the industrial output per man is greater in the United States than in any other country. Now let us change the viewpoint and instead of considering tons of fuel per capita

let us consider tons of fuel per square mile of area of the country. We leave it to our readers to calculate the figures. Without figuring at all, it is at once evident that the sequence of the figures for the different countries is entirely upset. What does this mean? Nothing more than that this country is very much less industrially populated than England or Germany and that the cost of transportation between the different industrial centers among each other and between industrial centers and sources of raw materials and markets respectively must be very much greater. In parenthesis it may be said that just this consideration explains why in the chemical industries certain things are possible in Germany which are impossible in this country.

If the economic value of a commodity is made up of place value, time value, and form value, and if place value is determined by transportation costs, it is thus clear that the place value is much more important in this country than abroad. This is necessarily true also for waterpowers. What has given Niagara its unique position among American waterpowers is its connection to the great lakes, with 3600 miles of shore line and navigable to the very docks at Niagara. The least expensive sort of transportation is thus provided for Niagara products to markets representing nearly half the population of North America, while the least expensive supply of raw materials is provided in many cases by the same water way, quite aside from the railroads running from Niagara in all directions.

This journal pledges its full support to any sensible waterpower development in any part of the country. But as things are at present, we must insist that, as a matter of fact, among American waterpowers Niagara Falls is in a class by itself. It is the place value of Niagara Falls which in conjunction with the available power makes it a national asset of unique economic value to the American nation. If the waste of power at Niagara is continued in future as heretofore, the only real loser is the whole American nation.

Value of Continuous Operation in Ore-Testing

Engineers experimenting with the flotation process are having their attention drawn to the value of continuous operation on a small scale in order to secure the most reliable data. It has been customary when making preliminary tests by the agitation-froth method, for example, to use a small single-cell machine and a few ounces of ore, keeping the pulp in closed circuit until no more froth is obtained. From such tests we get an approximate idea of the efficiency of oils, grade of products and general applicability of the process.

On the other hand there are certain factors which are not determined by such tests on a single-charge system. In practical application of the process various flow-sheets may be employed: A rough concentrate from several cells may be cleaned in another set; a middling product may be returned continuously and combined with the original feed; oily water may be recovered from concentrate or tailing, or both, for re-use; in short, commercial practice varies from the conditions of small

tests by introducing factors that may have a cumulative effect not observable in an experiment with a single charge. The latter will not reveal the effect on the grade of concentrate caused by continuous return of middling, nor will it show the influence on oil consumption produced by use of recovered water. Therefore continuous testing on a small scale is advocated in order to observe the cumulative effect of certain factors and permit correct deductions.

To a certain extent the same principle applies to other metallurgical work. In cyaniding, for example, continuous operation shows the chemical effect of certain inconspicuous elements or compounds in the ore which may exert their full influence only after they have accumulated in solution. The same is true of smelting, where the recovery and retreatment of by-products acts as a concentration process for deleterious substances that are not in evidence in the beginning of operations. Copper and zinc leaching and electrolytic deposition are other examples of processes in which complete information cannot be obtained by intermittent or charge tests. It has long been recognized that so-called "full scale" tests are not essential for preliminary investigations, but the principle of continuity on a small scale seems to be sound in cases where it is at all practicable. Where it is not, refined chemical analysis of the ore will be of marked assistance in forecasting the necessary precautions and the probable results.

Need of Ball-Milling Data

The ball-mill is making a strong bid for popularity as a crushing machine, and some of its advocates enthusiastically see the beginning of the end of stamps, Chilean mills, Huntington mills and other competing types of crushing and grinding apparatus. Considering the comparatively recent advent of the modern type of ball-mill, its performance excites interest and admiration and lends color to the claims of its optimistic supporters. There is no doubt that the machine will grind ore in large quantities and effect a satisfactory reduction in size at one passage through the mill. Due to the rapidity with which the crushed ore is removed from the crushing zone and discharged from the mill, the product is granular and well adapted to gravity concentration or flotation.

Aside from figures on tonnage, screen analysis and power, however, data are meager; and such as are available have only local significance. Installations are comparatively new as well as few, and mills have not been in operation long enough to afford reliable data on cost and efficiency in comparison with other types of grinders. It would be instructive, for example, to compare in every essential detail the work of the modern ball-mill with that of the Chilean mill in the Cripple Creek district where the latter has shown a remarkable performance.

Time and experience will verify the correctness or falsity of the figures on mesh-tons crushed per unit of power and the cost for repairs on ball-mills, and afford some basis for comparison with other machines. Meanwhile there is an absence of data and exact knowledge

on the most economical load of balls and size of balls for a given size of mill, as well as the correct ratio of the different sizes of balls in the total load. Determination of these factors would indicate the correct procedure in adding new balls to the load, not only as to quantity but also as to ratio of sizes.

It would seem, for example, that there is a correct ratio of sizes that will fill the grinding zone to the best advantage, giving the proper percentage of voids and the proper number of points of contact for efficient grinding. Assuming a mill to have been started with ball sizes in correct ratio, it would seem to follow that future additions of balls should be of such sizes and quantities as to maintain the original ratio. In practice, however, it is not uncommon to replenish the supply by adding only the largest balls, on the assumption that they will be reduced in size and keep the ratio constant.

Is this assumption correct? If we fill a cylinder with balls of, say, three different sizes, it will be found that the number of each size that can be introduced increases with startling rapidity as the size decreases. Assuming this condition to represent the desired ratio of sizes for efficient grinding, it becomes apparent that the largest balls, which are least in number, cannot be depended upon to furnish the requisite supply of small balls which originally existed in much greater number. If this is true, then small as well as large balls should be supplied to keep the crushing load constant in weight and in ratio of ball sizes.

The whole subject of ball load is worth investigation for the purpose of securing definite data on the most efficient manner of operating ball-mills. The matter could well be investigated in the testing laboratories of our schools of mines, or by large operators, or even by the manufacturers.

The Pig Iron Production Statistics

Pig iron production in the United States in 1915 is officially reported at 29,916,213 gross tons, according well with the estimate of 29,900,000 tons made in our review at the beginning of this year. The year's output fell 3.4 per cent short of the output in the banner year 1913, 30,966,152 tons, but the output in the second half of 1915, 17,682,422 tons, broke the record for a half year, 16,488,602 tons, in the first half of 1913, by 7.3 per cent. The present indications are that 1916 will show an output close to if not quite 40,000,000 tons, which would break the calendar year record by 29 per cent.

The sharpness of the swing from Bessemer to basic open-hearth steel is shown by the fact that while the output of basic pig iron in 1915, 13,093,214 tons, broke the previous record, made in 1913, by 4.4 per cent, the Bessemer output, 10,523,306 tons, fell short of the production in seven of the preceding years, and was but a negligible amount in excess of the output in 1902. The present year will show as large an output of Bessemer iron as the existing Bessemer-steel-making equipment can consume, but as some of the equipment has passed to the scrap heap and some has been diverted to the

duplex process it is a question whether the output will equal that in the banner year 1906, 13,840,518 tons.

The large steel works and even the moderate sized works, are practically self-contained as to pig iron. The tonnages made for sale, chiefly by regular merchant furnaces, as only a few steel interests, exceptionally placed, sell any pig iron, was as follows in 1915, with the proportion the merchant iron constituted of the total output:

	Gross Tons	Per Cent
Basic	1,747,265	13.3
Bessemer and low-phosphorus	871,730	3.3
Foundry	4,801,711	95.7
Malleable	829,921	100.0
Forge	174,355	52.2
All other	158,025	54.6
Total	8,583,007	28.7

The tonnage designated above as "all other" included spiegeleisen, ferromanganese, direct castings, etc. While the merchant production was 54.6 per cent of the total there is little doubt that more than one-half the spiegeleisen and ferromanganese was made by steel interests.

The production of ferromanganese in the year was 129,072 tons, breaking the previous record of 125,378 tons, made in 1912, by a small margin, but the production in the second half alone, 83,628 tons, was undoubtedly far in excess of the tonnage made in any preceding half year, and represented fully 70 per cent of the maximum requirements hitherto experienced, in 1912 and 1913. While the production of steel is much larger, the means employed at many works for getting along with smaller proportions of ferromanganese are probably sufficient to reduce materially the total consumption of ferromanganese in proportion to the steel output. The use of spiegeleisen and ferrosilicon, for instance, has been greatly increased.

The statistics of the tonnage of iron delivered molten shows that there is very large employment of the direct metal process. Of the total output of Bessemer and low-phosphorus pig iron the tonnage delivered molten was 70.7 per cent. Making allowance for a relatively small tonnage of Bessemer that is delivered molten by merchant furnaces to ingot mold foundries, and deducting an estimate for the low-phosphorus output, it would appear that the steel interests used about 78 per cent of their Bessemer pig iron output as direct metal. The remaining 22 per cent of iron that was cast was not all "Sunday metal" by any means, as commercial conditions were such in the early months of the year that a considerable tonnage was doubtless cast for stock, to be carried weeks or months. A year like the present will probably show a much higher proportion than 78 per cent.

Of the total production of basic iron in 1915 73.8 per cent was delivered molten, the highest proportion yet shown. Substantially all the merchant basic iron was undoubtedly cast, so that the 9,648,769 tons delivered molten may be compared with the 11,345,949 tons produced by steel interests, showing a proportion of 85 per cent direct metal, and leaving room for the introduction of very little additional refinement in making the blast furnace and open-hearth furnace work hand in hand.

Power from Niagara Falls and from Other Sources

To the Editor of Metallurgical & Chemical Engineering

SIR:—Are we not becoming unduly excited over Niagara power? Can we not have a discussion on the cost of power from various sources?

For example, natural gas sells for 5 cents per 1000 cu. ft., or less, in some sections of the West Virginia field. With the most efficient type of gas engine it would seem as though power from this source might work out as cheap as Niagara power. And salt is at hand.

And with the Mond producer-gas process gas seems almost a by-product—without cost—of a chemical plant producing a very high yield of ammonia, together with the usual tar products, and coke. Locate such a plant on a culm bank at the mine, convenient to salt, and low costs should result.

And then what is the matter with other water powers? Is not the Mississippi Power Co. at Keokuk, Iowa, looking for business? What about Massena, N. Y.? There are doubtless many locations in our own state (the upper Hudson, for example) and in New England where developed and undeveloped large and small powers are available.

Finally, it ought to be possible to buy current of some of the great central-station companies in our larger cities. Prices approximating $\frac{1}{2}$ cent per kw-hour—for certain uses—have been rumored. Of course, any such rate would only apply to those hours of the day when the regular lighting and power load is unusually light. Here regular service takes care of "overhead charges," so that anything in excess of coal costs, plus additional labor, wear and tear and supplies, should be profitable.

What does Niagara power cost the consumer?

Congress and the Dyestuff Situation

To the Editor of Metallurgical & Chemical Engineering

SIR:—The Right Honorable, the LXIV Congress is now in session. It assembled on Dec. 6, 1915, and adjourned for the holidays on Dec. 17. During that period 6848 bills were introduced of which 4144 (which sounds almost like four-leven-forty-four) were pension bills of which practically every one had been already presented to the pension office and rejected. One honorable member is the happy father of 208 of these bills. There were also introduced 198 bills changing military records, which are increases in pensions, and 1037 bills for claims which the United States Court of Claims had not regarded as sufficiently justified to approve. There were 718 local bills in which the people of the United States had no interest whatever as, for instance, one (H. R. 409) "authorizing the Secretary of War to donate to the City of Elsberry in the County of Lincoln, Mo., two bronze cannon or field pieces, with their carriages." It requires the deliberations of the 434 members of Congress at \$7,500 per year plus mileage to determine the future of Elsberry's hitching post! Of the 758 additional measures proposed and called for politeness' sake public bills, over one-half of them were, in point of fact, of private rather than public interest. I have these details from the bulletin of the National Voters' League.

Now the only possible good to come from these enact-

ments is Votes for Congressmen. The Pension Department and the Court of Claims are discredited and their work made of no avail; the lavish waste of money is like nothing more sober than a drunken sailor, and if it were not for the inestimable boon of having the present incumbents remain in the place of others who might be elected to succeed them in Congress after the next election, it would almost seem as though the money were spent for nothing.

These things give us something of a jolt. And yet, these gentlemen are the real representatives of the people; they are the means whereby democracy is justified—or fails. Congress is *us*, and if we do not like it let us at all events quit boasting and stop complaining. Neither will do any good. It all comes back to abuse of ourselves, for these are our representatives and we have elected them. Our Congressmen are our contribution to Democracy. The Civil Service men have nothing to do with what the gifted orator calls the In-stye-tootun o' Liberty; neither have department chiefs nor cabinet ministers. Congress is the people; and there's many a conscientious, able and earnest man in that body.

Then what's the matter with it?

Despite all that I have said there isn't anything in particular the matter with Congress. The matter is with us, us citizens. We haven't kept watch; haven't paid attention to what Congress did. It has not been interesting and so we have let the whole thing go by the board and we have satisfied our consciences by kicking at the politicians. Of course, some manufacturers have taken an interest in Congress, a very selfish interest that hasn't done Congress any good, but we do not refer to the lobby when we refer to patriotic interest. We have just let things slip along until bad practices have crept in. Then they have become general; like the bribery of dyers. We do not pay any attention to Congress until something important like war or a question of honor, or a general welfare or a tariff bill comes around; and then we expect Congress to act. Now Congress with the best intentions does not know what we want—unless we are manufacturers, and then Congress is likely to learn that we want more protection than a mud-turtle-porcupine hybrid. Otherwise we do not tell Congress anything. Congress knows (by experience, probably), that if we had a civil war record we should probably have put in appearance already, and if we do not want a position or some privilege or advantage, then we have no business with Congress. And Mr. Congressman addresses himself to the only people who seem to have business with Congress, to wit: those who want money and those who want favors. No wonder there are so many special bills; those are the very bills that count—to the Congressman. "Take all this yawp and hullabaloo about the dyestuff situation," he is likely to say. "People are making just the same kind of a noise that they always do whenever there is a tariff discussion." Mr. Congressman has heard that noise before and he wants to know why it means any more than it usually does? And if there isn't a single textile mill of any importance in his district, which is usually the case, what's the use, Mr. Congressman wants to know, of making such a fuss about it? Where does he come in? You see, half the Congressmen, irrespective of party, are built this way and think this way. Experience in public life has taught them what the public wants, which is pensions and favors. Then, if a man keeps regular with his party and looks after the boys in
